Three objections may be cited against the method, the most important being the possibility of producing drug sensitivity. It is inevitable that a small number of cases will be so affected, but the incidence is likely to be less than 5% judging by the published figures. In any case sensitization, if it is going to occur, is most likely to do so on or about the 8th day of administration, and by the continued exhibition of small doses (Tate and Klorfajn, *Lancet*, 1944, **2**, 553) the patient may be desensitized.

The second objection is the possibility of blood dyscrasia, but this is extremely unlikely and can be guarded against by regular medical supervision. The third objection, theoretically possible but extremely improbable, is harmful effect of the drug on the foetus. There has been no literature published to suggest, however, that even where prolonged and vigorous courses of sulphonamide chemotherapy have been given during pregnancy there is any untoward effect on the foetus. In the dosage described the amount of sulphathiazole entering the foetal circulation must be so small that the possibility of damage can be discounted.

Pyelitis of pregnancy is only cited as one example of where small and long-continued doses of sulphathiazole may be usefully employed for what virtually is a temporary chronic urinary bacilluria. Patients with indwelling catheters come into the same category, and there are private reports of the value of this method in patients with prolonged urinary infection where no underlying pathological condition can be found. In these cases or where surgical interference is not possible, prolonged use of small doses of sulphathiazole has proved effective. A dosage of the same order can make old age much more tolerable for the unfortunate victim of prostatic hypertrophy, nocturnal frequency being markedly reduced.

I am informed that dermatitis herpetiformis is an example where the same therapy has proved of value, although it seems possible that penicillin may be more effective in the latter condition.—I am, etc.,

Medical Department, May & Baker, Ltd. R. J. Eadie.

Sulphonamides and Measles

Sir,—I was very interested in Dr. Frankland West's letter on the above (April 21, p. 567). During the recent epidemic of measles I used sulphathiazole as a routine in about 70 cases, of which only two developed pneumonia. (These, however, made a rapid recovery.) The dosage for children of 1 to 6 years was 1/4 tablet four-hourly.

My observations have not shown that the present epidemic has been any less severe than any of the epidemics during the last ten years.—I am, etc.,

London, N.W.10. L. Sheldon.

Nurses and Tuberculosis

Sir,—You recently afforded me the courtesy of your *Journal* (March 24, p. 424) for a letter on this subject. The General Nursing Council for England and Wales, of which I am an elected member, has to-day (April 27) made it a requirement of hospitals approved as training schools for nurses that their student nurses shall be medically examined, including *x*-ray examination of the chest, either shortly before or on entry to training, the *x*-ray examination to be repeated at intervals of not more than 12 months. The Council also recommended the adoption in all training schools of the Memorandum on the Supervision of Nurses' Health issued by King Edward's Fund for London.

An important milestone in safeguarding nurses' health and improving living conditions has thus been passed. These measures will help, but nothing short of an entirely new approach to the training of nurses will effectively stem the 60% leakage, which is the cause of the shortage of nurses. Over 20,000 entrants have to be recruited each year in order to provide the average of 7,000 nurses who become State-registered annually and qualified to practise nursing.—I am, etc.,

London, W.2. Evelyn C. Pearce.

Shall We Nationalize Medicine?

SIR,—Dr. Charles Franklyn's letter (April 21, p. 570) implies there are only two alternatives from which to choose, "Shall we nationalize medicine?" or "Shall we commercialize medicine?" He seems to have been unfortunate since leaving the same hospital as myself—St. Thomas's. He draws a picture of practice to-day as being a sheer commercial "ramp." This, I am convinced, is incorrect. The vast majority of medical men are honest, hard-working, and friendly to each other. The average practitioner spends most of his professional life in one place, and does not build his reputation upon the sands of sharp practice.

After a period of Service medicine in the last war, house appointments subsequently, and general practice in this town since, I state emphatically that I have experienced the same friendly spirit in all three, and that whatever competition exists is co-operative and not "cut-throat." We all want to try to find the best way of bringing the best help to the greatest number, but ordinary practitioners like myself begin to have grave and serious doubts when zealous planners of Dr. Franklyn's type start bleating about "an assured position and an allotted task." Allotted by whom?—I am, etc.,

Bournemouth. E. D. GRANGER.

Obituary

GARNETT WRIGHT, M.B., F.R.C.S.

We regret to anounce that Mr. Garnett Wright died on April 29 at the Salford Royal Hospital, to which he was for many years honorary surgeon. He joined the B.M.A. in 1907 and held office as vice-president of the Section of Surgery at the Manchester Annual Meeting in 1929.

He received his medical education at Edinburgh University, and after winning prizes and medals during his student career graduated M.B., Ch.B. with honours in 1900. He then came south and for six years held resident surgical posts at Weston-super-Mare, Wolverhampton, and Stafford, at Ancoats Hospital, Manchester, and finally at the Leicester Royal Infirmary. He then settled in Manchester in consulting practice as honorary surgeon to Ancoats Hospital. At a later date he transferred his work to a greater sphere of experience at the Salford Royal Hospital. While working in house appointments he obtained the F.R.C.S. diploma in 1905. No surgeon from other schools than Manchester who settled in that city won such success in professional life. Of quiet, unassuming nature, he met with friendship from the physicians and surgeons and gained the good opinion and confidence of new graduates by his teaching power, sound judgment, proved surgical skill, and attractive personality and presence. He took part in the scientific discussions held in Manchester, and was in turn president of the Pathological Society and the Medical Society; as a committeeman and president he exercised unusual influence for good in their welfare and success. He was honorary surgeon to the Royal Deaf Schools at Old Trafford, where his work was greatly appreciated, and consulting surgeon to the Eccles and Patricroft Hospital.

Garnett Wright was particularly interested in abdominal surgery, writing several papers on gastro-jejunal and allied subjects in the medical and surgical journals. He was very successful in his operations on the thyroid gland and took this subject, with a review of it, for his presidential address to the Manchester Medical Society in 1936. At the Victoria University of Manchester he held appointments at different times as lecturer in surgical pathology and operative surgery and as assistant lecturer in the whole subject. He was a Fellow of the Association of Surgeons of Great Britain, and in 1935 was responsible for publishing the report of its collective inquiry into gastro-jejunal ulceration.

On March 19 news was received in Preston that Lieut.-Col. **WILLIAM SIMPSON** had died in a yachting accident in Jamaica. A colleague writes: Recalling his intense and tireless energy, his sudden death came as a severe shock to all the medical men in the Preston district. He came to Preston in 1938 as the first obstetric consultant to the new maternity hospital of the Preston Royal Infirmary, and the great success of this modern, well-equipped hospital was in large measure due to his skill, his energy, and his personality. His work at the hospital, in neighbouring hospitals, in the clinics of the Lancashire County Council and the Preston Corporation, satisfied the most captious critic. Tall and powerfully built, he gave doctors and patients alike that feeling of confidence which is the hall mark of the perfect consultant. In spite of successive nights spent in dealing with emergency cases, he appeared full of energy and vitality. He was always ready to help the practitioner in his obstetric difficulties, and his practice of midwifery was a pleasure to see. Before coming to Preston he had held appointments in Glasgow, London, and Barnsley. In the last-named town he had been associated with Dr. F. A. Sharpe, the late M.O.H. of Preston, who predeceased him but a few weeks. A graduate of Glasgow in 1923, he proceeded to the M.D. in 1927, and obtained the D.R.C.O.G. in 1936. He was interested in the Territorial Army, and at the beginning of the war held the rank of major. He left Preston in the latter part of 1940 to take up his duties in the R.A.M.C., and at the time of his death he was the A.D.M.S. in the Bermudas. He died in his early forties. His friends will cherish his memory and mourn the passing of one whom they could ill afford to lose: in life respected, in death regretted, by all whom he had served so well.

We regret to announce the death of Dr. **HORATIO NELSON BARON** on March 25, at the age of 86, at Orford, Suffolk, where he had been in practice for 45 years. Born at Hungerford, Berkshire, he was educated at Blue Coat School and Queen's College, Oxford, and at King's College Hospital, qualifying M.R.C.S., L.R.C.P. in 1888. After serving for a time as a ship surgeon he settled in practice at Pailton, near Rugby, and went to Orford in 1900. He joined the B.M.A. in 1890, and was chairman of the former South Suffolk Division in 1926–7. Other appointments held by him were: vice-chairman of the East Suffolk Insurance Committee and chairman of the East Suffolk Panel Committee. He was a member of the East Suffolk County Council. Dr. Baron was a man devoted to his profession and much loved by a wide circle of patients, colleagues, and friends. He had the vitality of a man much younger than the years he carried so easily on his equable shoulders, and to the very end of a long professional life he kept up a keen intellectual interest in medical science. He was always proud of his family connexion with Lord Nelson, after whom he was named. He leaves a widow, two sons, and three daughters.

Dr. **HORACE LANCE FLINT**, of Mansfield, Notts, died suddenly on March 27 while staying at Scarborough. He was born in that town 63 years ago, where his father was in practice. Before taking up medicine he served as an apprentice engineer. After graduating at Leeds with honours in 1909 and doing several hospital appointments he joined a leading practice in Mansfield. He served his country from 1915 to 1918 in Egypt and France. He returned wounded, and later had the opportunity of working under Sir Thomas Lewis, gaining much experience in cardiology, holding an appointment later in the heart centre at the General Infirmary at Leeds. He obtained his M.D. and published a book entitled *The Heart—Old and New Views*, in the preparation of which he received much encouragement from Sir William Osler. On returning to practice in 1919 he was the first physician in Nottinghamshire to own an electrocardiograph, and was frequently called in in consultation in the county. Considerable interest was aroused in the town when a hunter owned by one of the Royal Family arrived at his house to be electrocardiographed (the first time this had been done on a horse); it was found to be suffering from complete heart-block and had to be destroyed. Dr. Flint served for many years as physician on the staff of the Mansfield General Hospital. In 1937 he had an attack of coronary thrombosis; after many weeks' rest he resumed his full professional duties, but was obliged to forgo activities in recreation which he loved so well. The war years with the extra burdens they imposed increased the frequency of his attacks of angina. Last June he was obliged to give up work which was his life's interest, and had scarcely resigned himself to a life of inaction when he had his fatal attack. Dr. Flint combined the happiest qualities of the family doctor with a special knowledge of a particular branch of medicine, one of the best methods of ensuring a broad outlook on a specialty, and in the changes overtaking medical service, an example which, it is hoped, will often be followed. He leaves a wife, a married daughter, and two sons, one of whom is qualified in medicine.

Dr. **WILLIAM B. MARTIN** died at Old Colwyn, North Wales, on Easter Sunday, 1945. He was born at Cork, Ireland, on Oct. 21, 1882, being the eldest son of the late Lieut.-Col. John Martin, R.A.M.C. He received his medical education at Owen's College, Manchester, obtaining the English conjoint qualification in 1907 and the D.P.H. about a year later. After some time in private practice he contracted phthisis in 1912, from which he made a good recovery at Nordrach-on-Mendip Sanatorium, remaining there as assistant for about a year. After holding appointments at other sanatoria he became district tuberculosis officer to the Kent County Council in 1918, which post he held until 1937, when he had to resign owing to ill-health. He published several papers on tuberculosis, and, in spite of ill-health, retained his interest in this subject until the end. The numerous letters received testify to the esteem and affection felt towards him by his patients and those with whom he worked. He was a member of the B.M.A. since 1911.

Dr. **Thomas Marlin**, of Portland Place, London, who died at Bushey Heath, Herts, on April 5, was the son of David Marlin, of Butterburn Park, Hamilton. He studied medicine at the University of Glasgow, at University College Hospital, and at St. Bartholomew's Hospital, and graduated M.B., Ch.B.Glas. in 1909. He proceeded M.D. (with commendation) in 1912, obtained the D.P.H. in 1915 and the D.M.R.E.Camb. in 1920. His early appointments were those of house-surgeon at the Miller General Hospital and house-physician at the City of London Hospital for Diseases of the Chest. Later he was for a time medical officer in charge of the massage, electro-therapeutic, and light department at University College Hospital. He served during the last war as officer in charge of the massage department of No. 5 Orthopaedic Convalescent Camp, Salonika, and of the Special Military Surgical Hospital at Edmonton. In recent years Dr. Marlin had been physician in charge of the department for manipulative treatment and physiotherapy at the Hampstead General Hospital and was also honorary medical officer to the British Boxing Board of Control. He published in these columns a paper on "Some Common Complaints amenable to Spinal Treatment," and wrote a book in 1934, *Manipulative Treatment for the Medical Practitioner*. He joined the B.M.A. in 1915 and held office as vice-president of the Section of Radiology and Physiotherapeutics at the Annual Meeting at Cardiff in 1928.

Dr. **George Mackie**, of Wellington, Shropshire, died on April 10 at the age of 75. His father was a doctor in Inch. He was educated at Aberdeen University, and had been in practice at Wellington for nearly half a century, retiring only last year on account of failing health. He was a very popular figure in B.M.A. circles, both local and central, having been Representative of the Shropshire and Mid-Wales Branch 1919–34, again in 1936–9, and finally in 1941. He was a member of the Rural Practitioners' Subcommittee, 1925–30. At the Annual Meetings of the Association he was a regular and welcome figure, and will be remembered as one of the most joyous participants in the visit which the Association made to Canada in 1930 and on the world tour in 1935. He had been president of his Branch and was for many years chairman of the Shropshire Panel Committee. Mackie took an active part in everything which affected the interests of Wellington. It was largely owing to his efforts that the local cottage hospital came into being; he was very active on the St. John Ambulance Brigade; in the last war he was mobilized in the Territorial Force as a major, having been associated with the Volunteer movement from his earliest days in Shropshire. He was greatly interested in music and was president of the Wellington Orchestral and Operatic Society. In short, Mackie was a fine example of the good general practitioner who threw himself into every movement likely to advance the interests of his adopted home. A local colleague writes, "He was a man with a kindly heart, always ready to help and to look with compassion on the failings of another, but, above all, always able to smooth a difficulty with that rare gift he possessed in such abundance—a keen sense of humour." This appreciation will be shared by all who knew him, and their sympathy will go out to his wife.—A. C.

The medical profession, particularly in West Derbyshire, has lost a distinguished member in the person of Dr. **Walter Phillips**, of Matlock, who died suddenly on April 19. Born in Damascus in 1878, the son of the Rev. John Phillips, of the Irish Presbyterian Mission there, it was natural that these early influences should have a profound bearing on his later career. On the return of his parents to Belfast he entered the Royal Academical Institution there and later Trent College. Thence he passed on to Queen's College, Belfast, and graduated B.A. in 1898. His medical training was taken at Queen's and at the Middlesex and London Hospitals. He qualified M.B., Ch.B., B.A.O. in 1902, and immediately joined the B.M.A. After house appointments at the Belfast Royal Victoria and London Hospitals he followed in his father's footsteps to become a medical missionary of the same Church, and so began an arduous and distinguished career in China. His period of service there was interrupted only by a visit to England in 1912 to take his F.R.C.S., and on his return to the East he became surgeon to the General Hospital at Newchang and also port medical officer. His steady conscientious work did not pass unnoticed, and for his services during various plague epidemics he was honoured by the Chinese Government. On the outbreak of the Japanese "incident" in North China he returned home and carried on a busy general practice. He is survived by his wife, a son, and a daughter, the son being in the I.M.S. and the daughter in the W.A.A.F. W. H. M. writes: Very shy and reserved, it was not easy for one to get to know him, but once one had penetrated this barrier one found a true friend. His knowledge of medicine was not circumscribed, and he kept abreast of modern developments. Dr. Phillips found little time to contribute to medical journals, but he had literary talents of no mean order, and he wrote several short stories and novels which were much enjoyed by a small circle of friends but which his innate reserve would not allow to be published. He made an excellent conversationalist, and his wide travelling abroad made him an excellent linguist. Apart from his literary efforts, his hobbies were carpentry and the serious study of Nature on the quiet lonely moors near his home.

Dr. **James Whitelaw Alexander**, who died on April 24, was born in Glasgow in 1863, the son of Dr. Thomas Alexander. Educated at Glasgow University and Anderson College, he qualified L.R.C.P.&S. in 1886. He went to sea as surgeon in the British and Burmese Steam Navigation Co., which he eventually left to go to the West Riding Mental Hospital, Wakefield. Later he was at Rainhill Mental Hospital, where he became assistant medical officer. He took his M.R.C.P.Ed. in 1894. Then he settled in Armley, Leeds, as assistant to Dr. Coleman, whom he succeeded in practice. While in general practice he took the M.D.Durham. For many years he held the appointment as medical officer to St. Mary's Infirmary in Armley. He later gave up the practice but continued as medical officer to St. Mary's until he finally retired in 1933 and went to live in Scarborough, where he died. Running parallel with his busy life, he made the Army his hobby, starting in the early Volunteer days up to the formation of the Leeds Rifles of the West Yorkshire Regt. (T.A.). He held the Territorial Decoration. He trained and went to France with the 8th Battalion Leeds Rifles, which he commanded until being invalided home in 1917. He was awarded the D.S.O. and was twice mentioned in dispatches. Later he was transferred to the R.A.M.C. and posted Administrator to the Sunderland War Hospital, which appointment he held until the end of hostilities. He was retired with the rank of brevet colonel. He returned to Leeds and rebuilt the remains of the practice in Armley. Dr. Alexander was a great reader and was the proud owner of a very fine library, every book of which he had read, and from many of which he could quote with almost uncanny accuracy. He was buried in Scarborough with military honours. He leaves a widow and one son, Dr. Neil W. Alexander. A correspondent writes: He never wasted a minute in a very busy life as a doctor and soldier, and he was loved by all those whom he served in practice and by all those who served him in the Army. I think he had only two enemies—the Hun and the patient at Rainhill Mental Hospital who felled him with a crowbar when off his guard. I only regret he never lived to see the final defeat of his first enemy. He was a great clinician and a fine soldier.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

At a Congregation held on April 27 the following medical degrees were conferred by proxy:

M.B., B.CHIR.—P. B. S. Cooper, J. J. Fleminger, R. J. Harrison, M. B. McIlroy

UNIVERSITY OF EDINBURGH

At a graduation ceremony, to be held on June 22, the Hon. LL.D., will be conferred on Lieut.-Gen. Sir Alexander Hood, K.C.B., C.B.E., F.R.C.P., Director-General, Army Medical Services; also on Prof. Frédéric Joliot and Madame Irène Joliot-Curie, joint Nobel prize-winners, for their work on the induced radio-activity of common elements.

UNIVERSITY OF DUBLIN

The fourteenth John Mallet Purser Lecture will be delivered by Prof. B. A. McSwiney, Sc.D., M.B., F.R.S., dean and professor of physiology, St. Thomas's Hospital Medical School, in the physiology theatre of the School of Physic, Trinity College, on Wednesday, May 16, at 4.30 p.m. The subject is "Visceral Sensation."

The Services

Major-Gen. O. Ievers, C.B., D.S.O., retired pay, has been appointed Colonel Commandant of the R.A.M.C., in succession to Major-Gen. W. H. S. Nickerson, V.C., C.B., C.M.G., retired pay, who has attained the age limit for the appointment.

Surg. Lieut.-Cmdr. J. E. Hughes and Surg. Lieuts. J. H. Begg and G. L. Grove, R.A.N.R., have been mentioned in dispatches for gallantry, skill, and devotion to duty while serving in certain of H.M. Australian ships in the successful assault operations on the Lingayen Gulf, Luzon Island.

Capt. J. D. Fisher, R.A.M.C., has been awarded the M.C. in recognition of gallant and distinguished services in North-West Europe.

Liberated.—Major W. R. Henderson and Capt. P. E. R. Tattersall, R.A.M.C.

Repatriated.—Surg. Cmdr. W. Greaves, R.N.

CASUALTIES IN THE MEDICAL SERVICES

Killed in action at sea.—Capt. James Arthur Perkins, R.A.M.C.

Missing, presumed killed.—Temp. Surg. Lieut. Alexander Grahame Moray Wilson, R.N.V.R.

Wounded.—War Subs. Capts. P. Delap, K. G. Green, and C. W. Mearns, R.A.M.C.

Wounded or injured.—Temp. Surg. Lieut. G. Smith, R.N.V.R.

Fl. Lieut. **Sydney Wetherell**, who was killed by enemy action on April 8, was born in October, 1911. He studied medicine at Guy's Hospital and qualified L.M.S.S.A. After holding appointments as assistant in general practice he was commissioned as flying officer in the Medical Branch of the R.A.F.V.R. on Dec. 5, 1941. At the date of his death he was medical officer to a Royal Air Force squadron over-seas.

Squad. Ldr. **George Forbes Rees-Jones**, R.A.F.V.R., died on April 18, when serving as radiologist at a Royal Air Force general hospital over-seas. He was born in 1908, studied medicine at Glasgow University and University College Hospital, London, and qualified M.R.C.S., L.R.C.P. in 1931. Before being embodied for war service he obtained the D.M.R.E.

DEATHS IN THE SERVICES

Major-Gen. Sir **Charles MacWatt**, C.I.E., I.M.S.(ret.), died after a very short illness on April 14 at the age of 80. He had a long and distinguished career culminating in his appointment to be Director-General of the Indian Medical Service from 1922 to 1926. He received his medical education at Edinburgh University, where he graduated M.B., C.M. in 1886 and in 1897 passed the B.Sc. in Public Health. In 1911 he obtained the F.R.C.S.Eng. and in 1925 was elected F.R.C.P.Ed. He entered the I.M.S. in 1887 and saw much service on the frontiers of India at Hazara in 1888, Lushai 1889, and in the second Miranzai and Hazara expeditions in 1891, and received the Frontier medal with clasps. He rose steadily and reached the administrative grade as Inspector-General of Civil Hospitals in 1918, having already received the C.I.E. in 1916, and he had also been awarded the Kaisar-i-Hind Medal, first class. His sound administrative work in the Punjab led to his selection as head of the I.M.S. in 1922 with the rank of major-general, and in 1925 he was knighted, having also been appointed Honorary Surgeon to His Majesty King George V. On his retirement in 1926 Sir Charles MacWatt continued to live in India for some years and was adviser on medical and sanitary matters to his friend the late General Sir Ganga Singh, Maharaja of the Bikanir State. His high medical qualifications and sound careful administrative abilities were the foundation of his highly successful career. By his first wife, Blanche Mathilde, daughter of the late Lieut.-Gen. S. F. Blyth, C.B., he had two sons; he married again last year. He was a member of the British Medical Association for 47 years, and in 1891 contributed a paper to the *British Medical Journal* on gunshot wounds of lungs.

Major-Gen. **Henry Charles Rupert Hime**, late A.M.S., died on April 24. He was born on Nov. 8, 1877, son of T. W. Hime, M.D., and studied medicine at Leeds, graduating M.B., Ch.B. of Victoria University, with honours, in 1899, and taking the D.P.H. in 1908. He served as an officer of the R.A.M.C. in the South African War 1899–1902 and again in the war of 1914–18. He received the D.S.O. in 1917 and was created C.B. in 1934 when he retired from the A.M.S.; he was also awarded the Belgian Croix de Guerre for his services in the last war. Joining the B.M.A. in 1902 he held office as president of the Egyptian Branch in 1928–9. General Hime was Honorary Physician to the King in 1932–4. After retirement he lived at Bemerton, near Salisbury.

Medical Notes in Parliament

National Health Service Negotiations

In the House of Commons on April 19 Mr. **Lipson** asked the Minister of Health if he would issue a White Paper on the new proposals for a national health service which he had put before the British Medical Association and which they had circulated to their members, so that members of the House and the public might also have an opportunity to consider the Government's revised scheme. Mr. **Willink** said he had made it clear that there was as yet neither any revised scheme put forward by the Government on this subject nor any proposals of which publication in a White Paper or otherwise would be appropriate. Mr. **Lipson** asked if the Minister did not agree that he had informed the B.M.A. that if these new proposals were acceptable to their members he was prepared to recommend their acceptance by the Government, and was he treating the House fairly when the B.M.A. had circulated these proposals not only to their 70,000 members but to the public. Mr. **Willink** replied that he had made his position clear in the answers given the previous week.

Mr. **Aneurin Bevan** asked when the Minister proposed to tell the House what were the proposals he had discussed with the B.M.A. Mr. **Willink** said there were as yet no proposals.

Dr. **Summerskill** said Mr. Willink knew he had put these proposals to the profession and had undertaken, if they commended them, to sponsor them to the Cabinet. Mr. **Willink** answered that if Dr. Summerskill desired to challenge every statement he had made he could not deal with the matter further.

Lady **Astor**: Is it not true that this body is a trade union, like any other?

Sir **Waldron Smithers** asked the Minister whether, in view of the divergence of opinion about the proposals in the health White Paper and in view of the fact that many doctors, nurses, and patients were on active service, he would postpone the introduction of the Bill based on the health White Paper until after the General Election. Mr. **Willink** replied that he was not prepared to give any undertaking to that effect.

Mr. **McNeil**: Are we to understand, from the answer, that the Minister intends to introduce a Bill based on the White Paper before the General Election?

Dr. **Edith Summerskill**: The original White Paper?

Mr. **Willink**: I cannot say the date, and I cannot say what the eventual form of the Government's proposals will be.

Penicillin Supplies

On April 19 Col. **Lyons** asked to what extent penicillin was now procurable at the direction of a medical practitioner, and what facilities existed for its immediate availability when prescribed. Mr. **Willink** replied that the scheme for the wider distribution of penicillin was in operation. Supplies of penicillin had been issued through the distributing centres to nearly all the larger hospitals in the country and could be obtained, on request, by any hospital which had a suitable case. Supplies did not yet permit of the unrestricted distribution of penicillin through chemists and the usual trade channels. A practitioner who requires penicillin for a patient must therefore obtain it from a hospital and not through the issue of a prescription to the patient.

Research into Pneumoconiosis

On April 24 Mr. J. **Griffiths** asked the Minister of Fuel and Power if he had any statement to make about the efforts to combat pneumoconiosis among coal-miners. Major **Lloyd George** said that, following the report of the advisory committee on pneumoconiosis, arrangements had been made between his Ministry and the Medical Research Council for further investigations into the cause, prevention, and treatment of pneumoconiosis. The Council, in conjunction with his Ministry, had undertaken to establish and maintain a research centre in South Wales, and had appointed Dr. C. M. Fletcher to direct the work. He would take up his duties on June 1 next, and it was hoped to provide a small number of beds at a selected hospital. Additional physical and chemical investigations and reports would be made by inspectors of mines and other members of the Ministry staff. A joint committee of the Ministry and the Council had been appointed to assist in the development and co-ordination of the whole scheme of research.

Figures were not available of the number of workers lost to the industry by reason of silicosis and pneumoconiosis. He was informed that the number of new cases of silicosis and pneumoconiosis certified by the Silicosis Medical Board for total disablement and suspension from the industry on account of these diseases between Jan. 1, 1939, and March 31, 1945, was 6,483, and that during that period 647 death certificates were also issued by the Board. These figures included a relatively small number of surface workers certified under the Coal-mining Industry (Pneumoconiosis) Scheme, 1943.

Food Supply for Norway

Answering Mr. Harvey on April 20 Mr. G. HALL said the food situation in Norway was serious, though not catastrophic. It was not nearly so bad as in Holland or as it was in Greece just before the liberation. There appeared to be no widespread starvation among Norwegian children. Much of the relief provided by Sweden had been earmarked for children. Supplies of foodstuffs were being sent forward from Sweden as well as drugs and surgical instruments. Very considerable quantities of medical supplies were also being sent by the American Red Cross. Supplies from Sweden to Norway were not generally sent under the auspices of the International Red Cross, but to a body in Oslo called the Swedish Donors' Representatives, who distributed them through various charitable organizations, schools, and children's institutions. A delegate of the International Red Cross reported that the arrangements made by the body in Oslo ensured a wise and judicious use of the relief supplies.

Wheat Germ for "Medicinal Purposes"

On April 24 Sir E. GRAHAM-LITTLE asked the Minister of Health on what principle his Department advised allocation of wheat germ for the production of certain patent foods and medicines by a few favoured firms; what was the source of the wheat germ thus used; and what proportion that allocation bore to the available supply of wheat germ in this country. Mr. WILLINK said that the principle on which his Department advised was that any preparation for which wheat germ was allocated should be of such a composition that it was of value for medicinal purposes, and that it should be made available for such purposes.

The National Flour

On April 25 Mr. STOKES asked the Minister of Food on what date the standing committee on medical and nutritional problems made its recommendation with regard to the reduction of the extraction rate of wheat from 85 to 80%; and on what date the advice of the committee was specifically sought on this question.

Mr. TOM WILLIAMS: I understand that the committee was asked for advice on May 8, 1944, and that it submitted its report on July 27, 1944.

National Dental Service

Sir E. GRAHAM-LITTLE asked on April 26 whether Mr. Willink was aware that a statement of his proposals regarding a national dental service, promised by April 14, had not been circulated to the profession.

Mr. WILLINK said he understood that the profession's representatives began a few days ago the circulation of a report to those whom they represented of various matters which they had discussed with him. He wished, if possible, to know the profession's views on these matters before the Government considered what proposals they would make to the House on dentistry in the new service. He would keep in touch with the profession as to the best means of achieving this.

Medical Board for Pneumoconiosis

Dr. SUMMERSKILL reported on April 26 that a large number of workers suffering from pneumoconiosis awaited examination. She asked what action was being taken to expedite this. Mr. PEAT answered that Sir William Jowitt, in company with Major Lloyd George, had discussed this matter with the miners' representatives. With the assistance of the Minister of Health it had been possible to obtain the services of a few more doctors on the medical boards. Other special arrangements had been made with a view to expediting the examination of the applicants. The primary need was to get additional doctors with the necessary experience for this work. This was a matter of great difficulty at present.

Mr. OLIVER asked on the same day whether Sir William Jowitt knew of the anxiety felt by workers in industries which exposed them to the inhalation of silica, asbestos, and other dust when these men had contracted pneumoconiosis, and that no provision had been made to include them in the Workmen's Compensation Act. Mr. PEAT replied that the Minister would be prepared to consider some suitable extension of the compensation schemes for pneumoconiosis when an adequate number of doctors qualified to carry out the necessary medical examinations were available. Operation of the existing schemes was being severely hampered by the shortage of doctors. Sir William therefore could not contemplate extending them at present.

Admission of Medical Students

Mr. WILLINK on April 26 told Mr. Lipson that the average number of medical students accepted at the teaching hospitals for the three years before the war was 1,462. The number of admissions for the session to begin next autumn was not known. The medical schools would not complete the selection of candidates till later in the year. The average figure for the three years before the war included 226 women. Admissions for the present academic year were also 1,462, including 374 women. The numbers in medical schools could not be readily increased. There was great difficulty in obtaining staff, but the Ministry was doing all it could.

Mr. LIPSON asked the Minister to consider making use of public hospitals to give training to would-be women medical students who had been refused admission to teaching hospitals this autumn.

Mr. WILLINK replied that this was being considered.

Education in Scotland

Mr. JOHNSTON moved the second reading of the Education (Scotland) Bill in the House of Commons on May 1. He said that the object of the Bill was to bridge certain gaps in the Scottish educational system. It was a denial that education either began at 5 or ended at 14 years of age. This was a machinery Bill, providing for nursery schools, primary schools, compulsory secondary education up to 16, and after-school education. There would be certain ancillary services and free transport to and from school or college. There would be a medical inspection at the junior colleges, and free medical treatment, including the provision of spectacles. Scholarships, bursaries, and other allowances might be paid to persons over school age; this would cover students at universities and central institutions.

The Bill was read a second time.

Food of British P.O.W.s

On May 1 Sir JAMES GRIGG answered a series of questions regarding the rations supplied to and the treatment of British prisoners of war in camps in Germany. He said that all ex-prisoners on reaching this country completed a questionary which enabled them to give information about the treatment they had received. They were returning in large numbers daily, and it would not be possible to collate the information derived from their reports for some time. Numerous representations had had to be made to the Germans during the course of the war about breaches of one or other of the articles of the Geneva Convention. He gave particulars of the food given to our prisoners by the Germans in a reply on March 2. Information received recently suggested that even these rations had been reduced since then. Owing to the disintegration of the German administration and transport system during recent weeks, and the large-scale compulsory transfers of our prisoners of war, it was impossible to make any statement of general application at present.

Casein Hydrolysate for Starving Children

On May 1 Sir JAMES GRIGG informed Mr. Parker that he was aware that casein hydrolysate was used with success in Calcutta during the recent famine to revive moribund individuals and restore them to health; and that attempts were now being made to supply it to the inmates of concentration camps in Germany and to Dutch civilians, both in the standard form and in a form suitable for intravenous injection for cases *in extremis.*

Civilian War Casualties

Mr. HERBERT MORRISON states that from the outbreak of the war to date the civilians killed or injured by enemy action in the United Kingdom numbered 146,760. Killed or missing, believed killed, were 60,585, including 26,920 men, 25,392 women, 7,736 children under 16, and 537 unclassified. Persons injured and detained in hospital numbered 86,175, including 40,736 men, 37,816 women, and 7,623 children under 16. In the London regional district the casualties were 80,507.

Medical Relief for Channel Islands

The Red Cross relief ship *Vega*, in her fourth voyage to the Channel Islands lately, carried medical and surgical supplies. Two doctors of neutral nationality, who will act as a medical commission to select sick persons for evacuation, travelled on this fourth voyage and should by now have started on their task. On her third voyage the *Vega* carried 1 ton of x-ray films, a consignment of hearing aids for the deaf, one consignment o miscellaneous medical supplies, and 1,400 litres of petrol for doctors' cars and ambulances. On her second voyage she carried 20 tons of mixed medical supplies and a small consignment of anaesthetics; on her first voyage 37 cwt. of mixed medical and surgical supplies.

Medical Examination before Oversea Service.—On April 10 Mr. JAMES GRIFFITHS asked the Secretary of State for War whether men of 40 years of age and over were subject to a special medical examination to ascertain their fitness for the conditions prevailing in the Far East before being drafted for service in that theatre of operations. Sir JAMES GRIGG said that no special medical examination was given to such men. The normal examination of all men posted over-seas, which naturally took their age into account, was designed to ensure that no one was sent abroad who was not medically fit for the duties he would be called on to perform.

Mass Radiography.—Mr. WILLINK said on April 19 that the number of mass radiography units that could be manufactured was still limited, nor was it possible at present to make available more than a proportion of the medical specialists needed to operate the system. It was not yet practicable to extend mass radiography facilities to the East Riding of Yorkshire.

Incidence of Tuberculosis.—Mr. JACKSON on April 19 asked the Minister of Health to institute inquiries into the increased incidence of tuberculosis as billeting young children and placing young children with elderly people who had the disease might be the cause of the increase. Mr. WILLINK said no special inquiry was needed, nor should the trend of tuberculosis be judged from incidence rates alone. In fact the number of deaths from tuberculosis was no higher to-day than before the war. The danger to which Mr. Jackson referred was recognized, and great care in billeting children was exercised by local authorities while evacuation was in progress.

Hospital at Dar-Es-Salaam.—Col. LYONS on April 25 asked about the insufficiency of accommodation and the inadequate and obsolete equipment at the European hospital at Dar-Es-Salaam and the high incidence of malaria contracted by patients therein; what report was made by a commission of inquiry upon the matter; and what steps were proposed. Mr. EMRYS-EVANS answered that as the result of the report of the committee referred to, which found the state of the hospital to be unsatisfactory, expenditure of £74,000 had been approved for the extension and improvement of the hospital buildings. Large orders for modern equipment have been placed in this country by the Tanganyika Government. These orders would be met as rapidly as possible.

Christian Science Nurses.—Dr. SUMMERSKILL asked on April 26 why certain individuals attached to the Christian Science movement had been permitted to call themselves nurses in view of the recent Act which limited the description "nurse" to those suitably qualified. Mr. WILLINK said he had not yet brought into operation the provisions of Subsection (1) of Section 6 of the Nurses Act, 1943, which would restrict the use of the title "nurse," or made regulations under proviso (*b*) to that subsection. When he did so it was his intention to require Christian Science nurses to describe themselves as "Christian Science nurses." An assurance on the matter had been given by his predecessor, and the House of Commons, in the Public Health Act, 1936, had given statutory recognition to Christian Science nursing homes. He thought the object of the Act would be sufficiently met by a provision that Christian Science nurses should be required so to describe themselves. There had been difficulty in bringing the regulations into operation, particularly from an omission in the drafting of the Act. He hoped to make the regulations at an early date.

Notes in Brief

Mr. Johnston has appointed a Scottish Committee of Inquiry into the provision made for children deprived of a normal home life. The committee includes Dr. Nora I. Wattie.

By 273 to 74 the House of Commons on April 17 refused to allow Dr. R. D. McIntyre to take his seat as member for Motherwell without being introduced by two sponsors. On the following day Dr. McIntyre appeared with two sponsors, affirmed and took his seat.

Mr. Willink is consulting his Medical Advisory Committee about future arrangements for the diagnosis and treatment of rheumatic diseases, with which spas are specially concerned. He says it would be premature to make any pronouncement on the subject at present.

Having regard to the substantial proportion of those entitled to vote who are serving in the armed Forces, elections to the Dental Board for some time to come would, Mr. Attlee states, not only involve great practical difficulties but inadequately reflect the views of the electorate.

There appear to be no fewer than 26 classes into which patients in E.M.S. hospitals can be grouped for the purpose of recording adequately at any time the number of Ministry of Health patients and the number of other cases, the total in-patient days, total out-patient attendances, and the number of *x*-ray examinations. This sounds formidable, especially to the non-administrator, but hospitals will be helped by the booklet *Emergency Hospital Scheme: Classification of Patients* published by the County Accountants' Society. The latest (3rd) edition is now available, price 2s. 6d., from the secretary of the society at County Hall, Chichester.

Medical News

The British Council has arranged the following lectures for doctors of the Dominions and U.S. Forces and members of the B.M.A. in Birmingham, to be held at the University Overseas Club: May 13, "The Problems of Peptic Ulcer; The Present Position as seen by a Physician," Dr. T. L. Hardy. June 3, "Cancer: Some Theoretical Considerations," Mr. Hugh Donovan. June 17, "Fat Embolism," Prof. A. C. Frazer.

A meeting of the London Association of the Medical Women's Federation will be held at B.M.A. House (Tavistock Square, W.C.) on Wednesday, May 16, at 8 p.m., when Lieut.-Col. Albertine Winner, R.A.M.C., will speak on "Social Medicine and the Women's Services in the Armies of Britain, Canada, and the U.S.A." Surg. Lieut.-Cmdr. Rewcastle, R.N.V.R., and Wing-Cmdr. Butler-Jones, R.A.F., will open the discussion. Medical men and women guests are invited.

The following meetings of the British Institute of Radiology will be held at 32, Welbeck Street, W.: Thursday, May 17, 7.30 p.m., annual general meeting, followed by ordinary meeting and presidential address by Dr. E. Rohan Williams, "The Planning of the Diagnostic Radiological Department in a Large General or Teaching Hospital"; Friday, May 18, 4 p.m., Dr. J. F. Brailsford, "Malignant Diseases of Bone"; 5 p.m., informal meeting of medical members to show interesting cases.

A meeting of the Eugenics Society will be held at the rooms of the Royal Society, Burlington House, Piccadilly, W., on Tuesday, May 29, at 5 p.m. Mr. Cyril Bibby will give an address on "Sex Education—Aims, Possibilities, and Plans."

The next quarterly meeting of the Royal Medico-Psychological Association will be held at Birmingham City Council House, Victoria Square, Birmingham, on Thursday, May 31, at 10.15 a.m., when papers will be read by Dr. Alfred Meyer and Dr. F. A. Pickworth on "Neuropathological Problems arising from Leucotomy" and "The Physiology and Pathogenesis of Amnesia" respectively. At 2.15 p.m. the retiring president will deliver his valedictory address entitled, "Some Observations on the Reduction of the Distinctions drawn between Mental Ill-health and Physical Ill-health."

A reception was held on April 17 at the Society for Visiting Scientists, 5, Old Burlington Street, London, W., for the Belgian professors on a fortnight's visit to this country as guests of the British Council. Among those present were: Profs. M. F. L. de Hemptinne and C. J. Jungers, Faculty of Science, Louvain; N. Goormachtigh and P. Govaerts, Faculty of Medicine, Ghent; V. Bohet, Professor of English, Liége; and P. T. Lambrechts, Faculty of Philosophy and Literature, Liége.

At the quarterly meeting of the Central Council for Health Education held at B.M.A. House, London, on April 19, the chairman, Dr. Arthur Massey, announced that Lord Woolton, Minister of Reconstruction, had accepted the invitation extended to him on behalf of the council by the Minister of Health to succeed the late Dr. Temple, Archbishop of Canterbury, as its president.

The American College of Chest Physicians has cancelled its annual meeting which was to have been held at Philadelphia in June.

In the course of a single day's session a mobile team operating from the Ministry of Health's blood transfusion centre at Leeds recently collected blood from 820 donors, all of whom were Service personnel at a military unit. This is the highest number of donors ever dealt with by one team during one working day. The team consisted of one medical officer, assisted by 12 nurses, a blood-grouping technician, and a clerk, and worked from 8 a.m. to 4.30 p.m. The next day the blood collected by the team was flown to the B.L.A. in Western Europe.

The following medical men have been adopted as Labour candidates for Parliament: Lieut.-Col. Leonard F. Browne, R.A.M.C., for the Penrith and Cockermouth Division of Cumberland; Dr. Stephen Taylor for the new Barnet constituency; and Squad. Ldr. S. Segal, R.A.F.M.S., for Preston.

At the request of the Netherlands Government, the Bernhard Baron Research Professor in the Royal College of Surgeons of England, Prof. John Beattie, is at present serving on the Advisory Committee of S.H.A.E.F. Netherlands Mission which is advising that Government on the measures necessary for the relief of famine conditions in Northern Netherland. Prof. Beattie has charge of the laboratory and chemical investigations and has been chosen because he has developed and tested in the College laboratories various forms of treatment for extreme cases. He has with him in Holland members of the technical staff of the College who are training Dutch technicians in the up-to-date technical procedures required in this important work of famine relief.

As a precaution against mistakes in replacing gas cylinders on anaesthetic apparatus or in connecting a pipe-line to the apparatus—e.g., to a cylinder of nitrous oxide instead of a cylinder of oxygen—the Ministry of Health suggests in a circular to hospital and local authorities that a second person, preferably a doctor, should examine the connexions, making sure all is correct and in order, and record the fact that he has done so in a book kept for this purpose. It is greatly to be hoped that hospital authorities will follow this or some equally reliable procedure.

Dr. J. G. Treharne Thomas, *M.C.*, has been promoted to the post of medical superintendent of Cambridgeshire Mental Hospital, Fulbourn, nr. Cambridge.

The Universidad Central de Quito, Ecuador, has created a Chair of the History of Medicine with Dr. Virgilio Pasedes Borja as the first professor.

The March issue of the *Irish Journal of Medical Science* is a Rotunda Hospital bicentenary number.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week the incidence of scarlet fever went up by 141 cases, of diphtheria by 127, and dysentery by 60, while notifications for measles fell by 4,441 cases, those for acute pneumonia by 91, and those for whooping-cough by 22.

The increase in diphtheria is the largest for two years. There were small rises in most areas: Lancashire had 27 more cases than last week, Yorks West Riding 25, and Northumberland 20. In York C.B. the cases rose from 9 to 27. Notifications of scarlet fever rose throughout the country except in the south-east and south-west. The only large fall in acute pneumonia was that of Yorks West Riding with 39 fewer cases than last week. Measles returns fell by the following amounts in individual counties: Yorks West Riding 687, Essex 495, Staffordshire 348, London 337, Middlesex 330; increases of the following amounts were also reported: Sussex 92, Cumberland 76, Southampton 60, Cornwall 47.

A general increase in incidence, rather than fresh outbreaks, was responsible for the breaking of last week's record total for dysentery. In London cases rose from 32 to 77 (St. Marylebone 41, Wandsworth 13). The other large returns were Lancashire 61, Yorks West Riding 37, Warwickshire 33, Staffordshire 29, Middlesex 26, Kent 23, Devon 23, Derbyshire 23, Essex 22, Gloucestershire 22, Oxford 16, Northumberland 14.

In *Scotland* the incidence of dysentery was 17 higher than last week, and of measles 43 higher. The largest returns for dysentery were: Glasgow 55, Edinburgh 30, Aberdeen 21, Inverness 10, Zetland County 19. The recent outbreak in the west end of Aberdeen, involving 252 cases, has been traced to a milk supply; no fatal cases were recorded.

In *Eire* a rise of 13 in the notifications of diphtheria, and 23 for whooping-cough, and a fall of 34 for measles were recorded. The rise in diphtheria was contributed by the outbreak in Leixlip, Co. Kildare, and by Lullymore Turf Camp.

In *Northern Ireland* notifications of scarlet fever fell by 26 cases and of diphtheria by 8.

Quarterly Returns for Northern Ireland

During the December quarter the births registered were equivalent to a rate of 22.7 per 1,000, this being 3.0 above the average of the five preceding fourth quarters. The infant mortality was 68 per 1,000 registered births, and 6 below the five-years average for the December quarter. Maternal mortality was 2.3 per 1,000 births, and 1.1 below the average. The general death rate was 12.5 per 1,000, this being 1.5 below the rate for the corresponding quarter of 1943, and 0.4 below the five-years average. Deaths from pulmonary tuberculosis and other forms of tuberculosis numbered 201 and 62, the former being the same as and the latter 2 in excess of the five-years average.

The provisional returns for the year show that the death rate during 1944, 12.8 per 1,000, was the lowest ever recorded in Northern Ireland. The infant mortality, 67 per 1,000 registered births, was also the lowest on record, and was 10 below the average of the five preceding years. The birth rate, 23.5 per 1,000, decreased by 0.7, but was 2.1 above the five-years average.

Week Ending April 28

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,426, whooping-cough, 1,190, diphtheria 564, measles 16,023, acute pneumonia 530, cerebrospinal fever 56, dysentery 486, paratyphoid 3, typhoid 3. One case of typhus fever was imported into the country.

No. 16

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended April 21.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

ANY QUESTIONS?

Monckeberg's Senile Degeneration

Q.—*A lady aged 60, with blood pressure about 250/130 and symptoms of cardiac deficiency, suffers from attacks of severe pain in both calves, coming on only with walking. X-ray films reveal slight calcification of the tibial arteries. Nicotinic acid upsets her. Would sympathectomy help?*

A.—This patient is suffering from Monckeberg's senile medial degeneration of the tibial arteries. The presence of calcification in the middle coats shows that the disease is well advanced, and there must certainly be a considerable degree of obliteration of the channels. It is not possible to do much at this stage of the disease. Sympathectomy would be of little use, and she is old for this. Great care must be taken of the feet to preserve the skin from injury. Papaverine is sometimes helpful in relieving the pain on walking.

Smoking and Hypertension

Q.—*In his article "The Antidiuretic Action of Nicotine"* (JOURNAL, *March 24, p. 403), Prof. J. H. Burn states that smoking raises the blood pressure. Would you kindly tell us if it definitely aggravates hypertension and should therefore be stopped?*

A.—An answer to a rather similar question was published in the *Journal* of June 10, 1944 (p. 801). The blood pressure has been observed to rise on the average about 20 mm. systolic and 15 mm. diastolic when a normal subject smokes two cigarettes, even though he is a habitual smoker. The pressure returns to normal within five to fifteen minutes. The rise is apparently due to peripheral vasoconstriction. No comparable data have been noted for the rise in blood pressure in hypertensive subjects on smoking. It is generally agreed, however, that tobacco smoking is *not* an aetiological factor in essential hypertension, and it is further stated that patients with chronic tobacco poisoning have a low blood pressure. There is, in fact, no evidence that smoking aggravates hypertension and no justification for stopping it in this disease. On the other hand, there is a great deal of evidence that the vasoconstrictor action of tobacco is harmful in effort syndrome, neurocirculatory asthenia, angina pectoris, Buerger's disease, and other disorders of the peripheral circulation, and that it should be stopped in these conditions. In theory it may also be harmful in wound shock if the blood supply to a limb is imperilled by arterial injury.

Giant Urticaria

Q.—*What is the most promising line of treatment for a case of giant urticaria, with irritating and crippling effusions into the feet and joints? Calcium has not helped. Are peptone injections likely to be of use?*

A.—Treatment of urticaria, and especially giant urticaria, is often unsatisfactory, as shown by the large number of different therapeutic procedures. The allergic theory provides for only a proportion of the cases, sensitiveness to food or focal infection being well-known examples. Common foods are not often causal factors, because of automatic desensitization to them: the scratch tests or passive transfer method of Prausnitz and Kuestner may help to solve the problem of the cause, but as in other allergic manifestations skin-testing never offers final evidence of aetiology. Elimination diets are more likely to be helpful. A psychological factor is so often present that a sedative mixture may be included. The investigation requires a detective's mind and application to seek out and possibly discover some unexpected internal or external determining agency. General measures should include treatment of the nervous system by rest, change of environment, or of work; and desensitization by non-specific procedures, such as intramuscular injection of peptone. Alternatively an acid mixture after meals, or peptone 7 grains one hour before meals. Adrenaline injections during the attack may be required, and, finally, focal infection should be treated if found.

Hunter's Test for Bile in Urine

Q.—*What is the technique for Hunter's test for bile in the urine (referred to in your recent annotation on the treatment of hepatitis —March 24, p. 415)?*

A.—The following description of Hunter's test is taken from the second edition of Dr. G. A. Harrison's *Chemical Methods in Clinical Medicine:* "In a centrifuge tube place 10 c.cm. of urine; if it is not acid, it must be made slightly so with acetic acid. Add 4 c.cm. of 10% barium chloride, mix, and mark the upper level of the fluid with a grease pencil. Centrifuge and decant completely. Add distilled water to the mark, mix thoroughly, centrifuge, and decant completely again. Stir the precipitate with 0.5 c.cm. of van den Bergh's diazo reagent by means of a capillary pipette of which the end has been sealed in the flame. Add 2 c.cm. of alcohol (absolute or 96%) and 0.3 c.cm. of 6% $Na_2HPO_4 . 12H_2O$. Mix and centrifuge. If bilirubin is present the supernatant fluid will be red, due to the formation of azobilirubin."

Vasomotor Instability

Q.—*A woman of 23 suffers from extreme vasomotor changes in the hands and feet, most marked in the fingers. In warm weather, or after exercise, piano-playing in particular, the hands become red, swollen, and painful. In cold weather she has a chilblain type of circulation. She has had all the recommended treatments, but they are of no avail. What can be done for her?*

A.—This is a most difficult problem in therapeutics, and success in treatment is uncertain. The patient evidently suffers both from the effects of vasodilatation which warmth induces in the digits and from vasoconstriction in response to cold. It is not at all clear that the degree of such changes is outside the limits of normal variation, and it is possible that the abnormal feature in the patient is her mental reaction to the variations in her circulation. It is suggested, therefore, that treatment along general lines with particular attention to the patient's personality and her orientation towards the circumstances of her life may prove the most satisfactory treatment. Neither vasodilator nor vasoconstrictor drugs nor surgical operation offer any rational or empiric therapeutic prospects in this condition.

Methods of B.S.R. Estimation

Q.—*There is much variation in the method of recording sedimentation rates (B.S.R. or E.S.R.). Is it legitimate to divide the results obtained by the 200-mm. Westergren method by 2 in order to obtain a percentage, so as to be comparable with other results expressed initially as percentages?*

A.—To divide the reading obtained from the Westergren method by 2 is not strictly correct in comparison with other methods. For practical purposes comparable results may be obtained providing the other methods calculate the percentage on the amount of plasma. For example, the figures given are from experimental results, the normal values showing the most divergence.

No.	Westergren Method; 200-mm. Tube. Plasma mm. (and mm. %)	Modified Zeckwer and Goodell Method; 10-cm. Tube. Plasma mm. %	Micro-method; 100-mm. Tube. Plasma mm. %
1	50 (25)	30	24
2	36 (18)	26	18
3	10 (5)	5	8
4	4 (2)	2	5

Trichomonas Infection

Q.—*What is the technique of "blueing" in resistant cases of trichomonas infections of the vagina? What strength of solution of gentian violet is used?*

A.—In resistant cases of trichomonas infestation, first the vagina should be irrigated or swabbed with a solution of sodium bicarbonate; it should then be dried and painted with a 1–2% aqueous solution of viola crystallina (gentian violet) or liquor tinctorum, which consists of crystal violet and brilliant green, 0.5% of each in equal parts of alcohol and water. The application may be made through a Cusco or Fergusson speculum according to the preference of the operator.

Unilateral Flush after Food

Q.—*A boy aged 2 years has since birth had a facial erythema almost immediately after beginning his meals. It persists for 1/2 to 3/4 hour after feeding and then clears. The part of the face affected is that extending from the temporal region downwards across the malar bone to the angle of the mouth—on the left side; it is about two inches wide and fairly well defined. What are the exact condition, aetiology, and treatment, if any?*

A.—This is a curious story, rather like the rare "jaw-winking" phenomenon in which a congenital ptosis is temporarily improved when the child opens the mouth. Jaw-winking is usually explained as an atavistic regression to a condition present in fishes. It may be, in the present case, that the area described as affected corresponds to a "gill-opening." Essentially, the description is of an unusual vasomotor reflex action, and, provided there is no underlying naevus or naevoid condition, there is no treatment.

Radium for Rodent Ulcer

Q.—*I have recently had a rodent ulcer excised, and the base cauterized by the electric cautery. I have been told that the use of radium may cause cataract. Is this so? And if so, is there no method of using radium that will prevent such a contingency? The ulcer was near the left canthus, between the nose and the eye.*

A.—There is no danger of a cataract resulting from the proper use of radium for a rodent ulcer in the situation given. As a rule, the dose reaching the conjunctiva is insufficient to produce any conjunctival reaction, so that it is quite certain that the lens—where the dose is still smaller—will be uninjured.

Consent for Operation on Minors

Q.—*Is it legally necessary or desirable to obtain the parents' consent before doing in a minor a lumbar puncture under a local analgesic for diagnostic or therapeutic reasons (e.g., relieving intracranial pressure)? If it is necessary, it would seem that consent should previously be obtained for many minor operations—e.g., exploratory puncture of the chest, opening a quinzy, giving of intraperitoneal saline—even though no anaesthetic be used.*

A.—In strict law even the slightest physical interference with the person of another is an assault, for which damages can be awarded in a civil action or punishment in a criminal prosecution. Most kinds of physical interference which would otherwise be assaults may be justified by the consent of the person who suffers them, and among these justifiable forms of interference are medical and surgical procedures which are not in themselves unlawful. As a minor cannot give a legally valid consent, his parent or guardian must consent for him. Consent must, to be valid, be given freely and with substantial knowledge of the nature and purpose of the interference. The law knows also, however, an implied consent. By placing a minor in hospital, a parent doubtless gives an implied consent to his treatment by reasonable measures which carry no material risk to health or life. Where the medical adviser proposes to adopt a measure which involves drastic interference and carries risk, he owes the duty of first obtaining valid consent. As in so much of our law, the line between ordinary measures of treatment to which consent may be assumed, and drastic (not a legal adjective this, but one selected for convenience) treatment to which special consent ought to be asked, cannot be drawn in general terms. Its precise position in each situation is a question of fact, and in drawing it a court would consider such factors as the degree of pain, disturbance, or risk involved; or whether the particular act complained of was a usual part of the treatment of the particular illness, so that the person who had the right to consent or refuse might reasonably be held to have agreed to it by the act of bringing his child for treatment; and the like. The doctor should always bear in mind the need for consent to a class of procedures which may here be loosely but not inappropriately called "serious." If he asks himself whether he, in the parent's place, would prefer to be given the chance of refusing consent, he will probably not go far wrong.

Fatigue after Removal of Ovaries

Q.—*A patient aged 45 had a fibroid uterus and cystic ovaries removed eighteen months ago. She menstruated regularly until her operation, and her blood pressure, taken at the time, was 132/71. She now has "palpitation" and a tendency to fatigue. Her heart and pulse are normal. Her blood pressure is now 135/98. I propose to treat her with hexoestrol mg. 1 t.d.s. Will this have any effect on her blood pressure?*

A.—A patient who has had the uterus and both ovaries removed is likely to suffer from menopausal symptoms. These most commonly take the form of headaches, hot flushes, and emotional disturbances, though palpitations and a tendency to fatigue may also occur. Hexoestrol in the dosage mentioned is likely to relieve such symptoms and to give the patient a general sense of well-being, and —provided anaemia is excluded, and treated if necessary—this would seem to be the correct treatment in this case. The dosage should be gradually reduced as the symptoms improve. It is unlikely, however, that this treatment will have any effect on the rising blood pressure. This patient is probably suffering from benign hypertension in a mild form, and it is likely that the pressure will continue to increase with age. Hypertension is common, and according to S. C. Robinson and M. Brucer (*Arch. intern. Med.*, 1940, **66**, 393) slightly over 40% of the adult population is actually or potentially hypertensive. In the case described the condition is so slight that no treatment is indicated, and it is doubtful if the rise of pressure is great enough to cause the symptoms of which the patient complains. The possibility of a functional element should not be overlooked, and reassurance will probably help the patient a great deal.

LETTERS, NOTES, ETC.

Climate and Burns

Dr. **FRANK MARSH** (pathologist, A.I.O.C., Persia) writes: In the *Journal* of March 10 (p. 344), Prof. Kenneth Black, in a letter on climate and mortality from burns, brings evidence to show that a warm climate lessens this fatal incidence. We "enjoy" a climate with a very hot summer, and, by European standards, a moderately cold winter. It is true that we see more fatal cases of burns in the winter, but I think the main reason is that in cold weather cooking fires are lighted *in the dwellings*, and in summer the cooking is usually done outside. A very common cause of severe and fatal burns among women is the explosion of a "primus"-type stove designed to work with kerosene, and used, through ignorance or misplaced ingenuity, with gasoline. Such accidents are infinitely worse when they occur in a small room than in the open air, judging from results. In the open a metal or dried mud screen is built round the fire as a wind shield, unnecessary indoors. Kerosene and petrol burns are usually very severe, and a certain proportion are not accidental but malicious; frequently the victim is young, well developed, and good-looking. It is not claimed that these latter are factors affecting the mortality unfavourably, although statistically, no doubt, a case could be made out. Dirt is an unfavourable factor associated with cold; a sweating skin is probably a relatively clean skin. Certainly the mortality is much lower in the warm weather, but I have always thought this variation due to a number of contributory causes—such as more clothing worn out of doors than indoors, the exceptional severity of indoor-inflicted burns, the concealment afforded by a small windowless room for malice, the greater danger of explosions, etc., in a confined space, and the absence of wind shields, etc. I do not think the climate—blameworthy as it is in nearly every respect—can take the whole burden for the high mortality in Glasgow.

Oedema of the Ankles in Hot Climates

Dr. **GEOFFREY HALL** (Cunderdin, Western Australia) writes: In the *Journal* of Aug. 19, 1944 (p. 262), I see a reference to swollen ankles in hot climates. You might be interested to hear of a phenomenon I have seen here in pregnant women. In my last 100 midwifery cases there was one case of pre-eclampsia with albuminuria, but the percentage of cases of definite pitting oedema of the feet in the absence of varicose veins or any local condition was 5. Swollen ankles in the absence of albuminuria or other signs of toxaemia developed in these 4% of cases in the last three months of pregnancy, and invariably the patient volunteered that the swelling came up in hot weather and disappeared completely in cold. Thus the syndrome is analogous to swollen ankles in hot climates. In my cases no doubt the pressure of the head on the pelvic veins produces venous stasis in the lower limbs and aggravates the condition, but I feel that in both instances the syndrome is primarily due to peripheral vasodilatation from the heat, with increased capillary permeability. I can find no reference to swollen ankles in the condition known as "heat disease," but as the treatment of this is sodium chloride, I wonder whether such treatment would be effective in the conditions under discussion.

Treatment of Supraspinatus Tendinitis

Mr. **J. R. ARMSTRONG**, F.R.C.S. (Ely), writes: In discussing the treatment of supraspinatus tendinitis your correspondent (March 31, p. 468) does not mention excision of the acromion. This procedure, described by Watson-Jones in 1943 (*Fractures and Joint Injuries*, 3rd ed., p. 418, Livingstone, Edinburgh), is a certain, and in some cases the only certain, method of dealing with these lesions. The supraspinatus tendon impinges on the overlying acromion in the middle range of abduction, when the tendon is swollen or inflamed. This pressure produces pain and causes the painful arc of shoulder movement which is a characteristic feature of supraspinatus tendinitis, with or without calcification. Moreover, these repeated small traumata further aggravate the condition of the tendon. The rationale of excision of the acromion is obvious. Supraspinatus lesions seem to fall into two broad classes: those which tend to clear up spontaneously and those which do not. In the latter class the results of injection of the tendon have, in my hands, been inconstant and disappointing. This contrasts markedly with the almost dramatic relief produced by excision of the acromion. The operation itself is comparatively simple, the post-operative convalescence is short, and the subsequent function of the shoulder is normal.

Electrically Induced Convulsions in Epilepsy

Dr. **H. PULLAR-STRECKER** (Falmouth) writes: The idea of "letting-off steam" under controlled conditions of time and place appears useful in selected cases. As a criterion, however, tables should have a third column, showing the average number of spontaneous plus induced convulsions per month. In the four illustrative cases given by Dr. Gerald Caplan (April 14, p. 511), such number is roughly as follows: B.I. 4.5; O.P. 8.5; M.T. 10; C.A. 4.

"PRIMARY ATYPICAL PNEUMONIA"

AN EPIDEMIC ASSOCIATED WITH MALARIA

BY

J. FLEMING, M.D., F.R.F.P.S.,
Lieut.-Col., R.A.M.C.; Officer in Charge of a Medical Division; Assistant Physician, Glasgow Royal Infirmary

E. W. LINDECK, M.R.C.P.
Major, R.A.M.C.; Medical Specialist

AND

I. H. EVANS, M.R.C.S., L.R.C.P., D.M.R.
Capt., R.A.M.C.; Graded Radiologist

(From a Military Hospital in Italy)

There is still considerable doubt as to what extent atypical pneumonia is a "new" disease in the sense that von Economo's encephalitis was a new disease in 1918, or whether until recent years these cases went unrecognized under such diagnoses as bronchitis, bronchiolitis, pneumonitis, etc. There appears to be considerable variation in the severity of the illness, and in some published series most of the cases were mild. Thus Campbell *et al.* (1943), while reporting one death in 200 cases, say that on the whole they were mild with infrequent complications, and among 75 cases occurring in a college Contratto (1943) reports that none was serious. It can readily be believed that the milder cases occurring sporadically may have gone unrecognized, but it is not so easy to see how, in its more acute manifestations, the disease could have passed the notice of clinical and radiological scrutiny, especially when encountered in an epidemic form.

The review of early reports in the excellent paper of Drew *et al.* (1943) makes it clear that similar cases were apparently noted from time to time in America, France, and Spain during the past 10 years. But it seems to have been a rarity in Great Britain, and only since the war began have frequent reports drawn attention to its prevalence. Most of the recent reports are from the Services, and the careful medical scrutiny which is given even to minor illness probably accounts for the identification of many mild cases which would pass unrecognized in civil practice.

Whether or not it was frequent but undiagnosed before the war, it seems that the increased incidence now noted is due to the opportunities for infective spread in the crowded communities inevitable in wartime, and it invites comparison with the influenzal pneumonia of 1918. Fortunately, atypical pneumonia so far has manifested as a disease of relatively mild incidence and low morbidity. It has been suggested (Army Medical Department Bulletin, 1943) that dietary deficiency may account for the increase in certain cases, but this certainly does not apply to the Services. Whether in debilitated populations the disease may develop more serious forms remains an uncomfortable possibility.

In a series of 125 cases Needles and Gilbert (1944) had one fatal case, which came to necropsy. The illness ran a typical course till the 11th day, and the patient then became dyspnoeic and cyanosed. Death occurred on the 18th day, and the main finding was a profuse purulent bronchiolitis. The authors point to the similarity between their cases and types of influenza described by workers in 1918–19.

Epidemiology

The present paper is based on a series of 112 cases treated in a military hospital while on service in North Africa and Italy. Only a handful were encountered in Africa, but during the first few months in Italy the numbers were such as to suggest an epidemic. Leishman and Kelsall (1944), in a review of their work in a hospital in India, report no case of atypical pneumonia in a total of 11,645 cases. This, in association with other reports we have been able to review, suggests that atypical pneumonia is a disease of temperate climates and is rare in the Subtropics and Tropics. It is generally accepted that atypical pneumonia is of virus origin, but no relation has been shown with any of the known virus diseases. The psittacosis virus has been suggested as a possible cause, but in Italy birds of any sort, not to mention parrots, are a rarity. In addition, atypical pneumonias have been noted in association with lymphocytic choreomeningitis, rickettsial infections, Rocky Mountain fever, influenza, chicken-pox, and other diseases thought to be due to virus infections. Howat and Arnott (1944) report seven cases of atypical pneumonia in smallpox contacts, and quote Reimann, Hewens, and Price, who claim that this syndrome may be produced by smallpox virus. It is perhaps worth noting that prior to the quasi-epidemic of atypical pneumonia here described there had been a large incidence of infective hepatitis, also a virus disease of unknown origin, and the two diseases were seen in comparable numbers throughout the period of investigation. We were unable to show any relation between the two. No lung lesions were found in a selected number of cases of hepatitis, and although two cases of atypical pneumonia developed mild jaundice, this is recognized as an occasional complication (Reimann and Stokes, 1939).

It is clear, therefore, that an atypical pneumonia may occur in association with most of the known virus diseases, but there is no evidence to show that primary atypical pneumonia is associated with any one in particular.

There was no case of cross-infection in any ward nursing atypical pneumonia, and no member of the staff was infected. We were, however, able to obtain some evidence of infectivity among patients admitted from the same units. Thus there were several groups from the same military units, many beginning on the same day, and therefore suggesting a common source of infection, and, in addition, evidence that others had been infected by their comrades. From a survey of 30 such cases, made up of groups from five units, it was possible to arrive at a probable incubation period, with extremes from 6 days to 12 days; the average incubation period was 10 days. It appears, therefore, that the disease is infective only during incubation, and that, when established, may, like infective hepatitis, be treated in general wards without fear of cross-infection. Vance *et al.* (1943) gave sputum and nasal washings from 12 patients to 5 volunteers intranasally. They failed to produce infection. This supports the view that the established disease is of low infectivity.

Onset and Course of Illness

The onset was marked in most cases by fever, malaise, and shivering (or a definite rigor), muscle pains, headache, anorexia, and, in a few, constipation and nausea. One case began with vomiting, one with diarrhoea, and a third had a small haemoptysis as the first sign of illness. These groups were distinguished according to the mode of onset:

1. Gradual onset with low fever, malaise, and some of the mentioned symptoms in a mild form (39=34.8%).

2. More sudden onset with pain in the chest and high fever. Two cases in which the lesion manifested at the extreme base had pain in the corresponding side of the neck as the initial symptom (39=34.8%).

3. In a third group the initial symptoms were masked by malaria, and were diagnosed by discovering a few rales in a patient who was not responding to quinine (34=30.4%).

The second group, who showed no evidence of malaria, had an onset severe enough to suggest at first malaria. These cases usually ran an acute course with high fever, and demonstrate that atypical pneumonia is not always a "benign" illness, unless one restricts the term to the question of morbidity and complications. The fever usually finished by rapid lysis about the eighth day, with extremes of 1 and 24 days. There was considerable debility in most cases, but 7 to 14 days after subsidence of fever they were able to be transferred to a convalescent depot, and were then seen a month later for further radiographs. Convalescence was continued if necessary till the lung fields were clear.

Age Incidence

In common with American reports, in this series we found a maximum incidence in the younger age groups, as is shown by the following figures:

Age Group:	15–19	20–24	25–29	30–34	35 and over
No. of cases ..	1	43	27	25	16

In this respect atypical pneumonia is quite unlike pneumococcal pneumonia.

Symptoms

Cough.—As an early symptom, cough, troublesome and non-productive, is described by other writers (Drew *et al.*, 1943; Meakins, 1943; Correll and Cowan, 1943; Leake and Blatchford, 1943), but in this series cough was slight or absent in 69 (61%), and in the remainder was never troublesome—that is, counter-measures were not required.

Rigors.—Of the 112 cases 59 had shivering at or near the onset, and in a large number—about 25% of the whole—there was a brisk rigor signalling a sudden onset. Discounting those who had a malarial complication, the remainder showed a similar onset, 50% having initial shivering, and about half of these a definite rigor. Unlike lobar pneumonia, the rigor, when it occurred, was not closely associated with chest pain, although in most cases there was pain of various types a few days after the onset.

Pain in the Chest.—Of the 112 cases 70 had pain of some sort in the chest. It was not so severe as typical pleuritic pain, and was found as a rule to be strictly localized to the site of the lung lesion. The majority had pain in the antero-lateral aspects in relation to the fan-shaped lesion spreading from the hilum. In others the pain was felt in the back, again on the side, and at the site of the lung lesion. In seven cases pain was felt in the supraclavicular region and in the neck; in five of these a lesion in the upper lobe was found, but in two others the lesion was situated on the diaphragm, indicating reflex irritation via the phrenic nerve. In three cases in which a dense lesion was found spreading from the midzone of the hilum the patients complained of a constricting pain across the chest at this level. Although pain was so frequent, friction was not detected in any case, thus sharply differentiating this type of lesion from that of lobar pneumonia, in which the pleural surface is usually involved early. This is in line with the view, long held by one of us (J. F.), that the so-called pleuritic pain is not due to friction between inflamed pleural surfaces but to a spasm of the chest musculature over the site of the lesion. The pain was not notably aggravated by cough or deep respiration, and only in one case was morphine required. In Meakins's (1943) cases this "non-pleuritic" pain only was noted, but Drew *et al.* (1943) found friction pain in four cases in their series of 50, and Markham (1942) found pleural involvement in three of 65 cases. It is evident that the atypical lesion does not usually spread to involve the pleura. Even when radiologically the lesion had apparently spread to the lung periphery no friction was detected.

Differential White Cell Counts: Percentages

Case No.:	1	2	3	10	12	20	25	27	28	35	36	39	51	53	56	64	66	74	82	84	90	92	93	98	100	110	112	118	119	120
Polymorphs	56	64	70	50	31	61	28	49	64	61	59	39	52	62	44	63	68	54	56	50	69	70	68	66	52	62	47	55	85	61
Lymphocytes	36	27	22	44	62	30	69	47	30	34	39	46	43	36	50	32	25	45	43	30	24	23	33	32	28	32	39	40	14	37
Monocytes ..	7	8	4	5	7	7	3	4	5	4	2	5	5	5	4	5	7	1	1	10	6	6	8	2	14	4	8	4	1	2
Basophils ..	—	—	1	—	—	1	—	—	—	—	—	—	—	—	—	—	—	—	—	—	—	—	—	—	2	1	—	—	—	—
Eosinophils..	1	1	3	1	—	1	—	—	1	1	—	—	—	1	2	—	—	—	—	1	1	1	1	—	4	1	6	1	—	—

Sputum.—The quantity and type of sputum were found to be roughly related to the extent of the lung lesion and to the severity of the illness in general. Thirty-four (30.4%) had no sputum throughout, but one of these was ill enough to be put on the "serious" list. All the others had a little mucous sputum early in the illness, but it was seldom notable before the third or fourth day, by which time it had usually become mucopurulent, and 24 on or about the fourth day had some blood present. In four the sputum at one point could be described as rusty! Drew *et al.* suggest that such a finding calls for a review of the diagnosis, but all were otherwise typical (e.g., Case 28).

Bacteriology of the Sputum.—In every case except one sputum culture produced a mixed flora. Pneumococci were present in almost every case, usually in association with streptococci; but frequently Friedländer's pneumobacilli, and less frequently *Micrococcus catarrhalis* and staphylococci, were also present. In one case Pfeiffer's bacillus was in association with pneumococci and streptococci, and in two cases only a few pneumococci were grown from scanty mucoid sputum. The almost constant presence of pneumococci raises the question of their pathological significance; but the course of the illness, uninfluenced by sulphonamides, the low leucocyte count, and atypical lung appearances, made it unlikely that they were more than the normal flora of the upper respiratory tract. One of us (J. F.) has shown that a low leucocyte count in the early stages of pneumococcal pneumonia is found only in extremely toxic cases, usually Types II, III, and related types. In such cases the lung lesions are as a rule massive and typical. Unfortunately, biological selectivity tests were not available to us.

Leucocytes.—Counts were made in 68 cases during the first 48 hours after admission (most of the cases were admitted on the first or second day of illness), and in many instances were repeated on the sixth and ninth days. The highest count was 13,600 per c.mm., and the lowest 3,400; 20 (16.9%) were under 6,000, 62 (55.3%) were under 10,000, and 5 were more than 10,000. These findings are similar to those of Meakins (1943), who found less than 10,000 per c.mm. in 73% of his cases; Leake and Blatchford (1943), who found counts from 6,000 to 9,000; and Correll and Cowan (1943), who found less than 9,000 per c.mm. in 55.5% and less than 12,000 in 95%. Haight and Trolinger (1943) state that while the count was low or normal at the onset, later they found mild leucocytosis. In the present series two were found to have an increase from 7,600 and 5,000 on the third day to 10,400 and 9,600 respectively on the sixth day, but most showed no notable change, and in several the count decreased—e.g., in one, 7,800 on the third day, 6,100 on the sixth, and 4,600 on the ninth. Shone and Passmore (1943) state that one of their cases had a leucocytosis of 61,000 per c.mm.; this must be exceptional. In 30 typical cases we made differential counts (see Table).

With few exceptions these counts reveal a relative lymphocytosis with a slight increase in monocytes. There was no eosinophilia and no primitive cells were noted. Moeschlin

(1943) finds a lymphocytic reaction to be usual in virus pneumonia (primary atypical pneumonia) between the 12th and 17th days. The lymphocytes may form 74% of the total white cell count on the 13th day, and then begin to fall. He also noted an eosinophilia as high as 10% on the 13th to 15th days. Similar changes are found in infectious mononucleosis, measles, and hepatitis. He points out that in pneumococcal pneumonia the lymphocytes are usually less than half the total of those present in atypical pneumonia, and suggests that this fact may be useful in differential diagnosis.

Cold Agglutinins.—Ramsay and Scadding (1939) and Turner *et al.* (1943) report that high titres of cold agglutinins were regularly found in primary atypical pneumonia. This promises to be of great value in differentiation. Under field conditions it was found to be impracticable to undertake this investigation for the series. In two cases with characteristic clinical and radiological findings cold agglutinins were absent.

Physical Signs

Most of our patients had sharp fever. The average duration of pyrexia was 8 days—ranging from 1 day to 24 days; in 51% it was 8 days and less, and in 81% 10 days and less. In many cases the illness began with high fever, in 82% reading more than 102° F.; 42 had peaks of 103° F. or more, the highest being 105.4° F.; only 8 of these latter had an associated malaria. In remarkable contrast to the high level of the temperature curves, there was little or no change in pulse or respirations. Brachycardia was not observed (Drew *et al.*, 1943; Meakins, 1943). Cyanosis and dyspnoea were unusual or absent, as was to be expected from the small amount of lung tissue involved. About 70% had frontal headache, which was sometimes very intractable and suggested meningeal irritation. Five had suffusion of the eyeballs, and slight labial herpes was noticed in 4 cases. Faucial congestion (3 cases), epistaxis (2 cases), jaundice (2 cases), and petechial rash (1 case) were also noted. Gastro-intestinal disturbance was rare, and occurred usually at the onset (anorexia, nausea, diarrhoea, and constipation). Six patients were notified as being seriously ill; but once the diagnosis was established there was little cause for anxiety, and the illness terminated quietly by lysis. There was no case showing albuminuria, and no diminution of chlorides was observed.

Enlarged spleen was found in only 8 patients, and 5 of these had an associated malaria. Owen (1943) noted an enlarged spleen in 8 of 16 patients, not associated with malaria.

Chest Signs.—Twelve patients had no detectable physical signs throughout the illness. They were found to have minimal lesions radiologically—either centrally, in a lobe, or closely applied to the hilum. Ten who had no signs during the first few days, when the lesion was still distal from the periphery, had detectable signs later, when radiographs showed spread to the lung surface. As has been generally noted, the most common finding was small crepitations strictly localized to the area of the lesion, and usually accompanied by a diminished breath sound. Next in frequency came harshness of the breath sound, and in many cases a soft tubular breath sound was heard. Occasionally, when the lesion was larger and denser, and especially if basal, the percussion resonance was diminished, but frank dullness was not observed. Since the lesion usually is relatively small and may occur in any part of either lung from apex to base, a very careful examination of the whole surface area is necessary. At first we failed at times to detect signs until radiographs had indicated the place, but latterly the significance of localized small signs had made the diagnosis possible before radiological confirmation. In no case was there any evidence of pleural effusion.

Complications.—Drew *et al.* in their series of 50 had three cases of otitis media and one of antral sepsis, and in common with other writers they found a secondary rise of temperature "on many occasions." Secondary temperatures did not occur in our series, and there were no complications, except in two cases which early in the illness developed mild transient jaundice. This absence of complications we ascribe in part to the routine use of sulphonamides, which for this reason, and for other reasons stated below, we recommend in treatment. Leake and Blatchford report that chemotherapy is ineffective, and that they had no complications. We believe that "chemotherapy" (meaning sulphonamides) and "no complications" are more closely related than is implied.

Treatment

We kept our patients in bed for 7 to 14 days after the temperature became normal, and continued convalescent care, usually in an adjoining convalescent depot, till the lung was clear radiologically. As full a diet as the appetite allowed was our rule, for there were no gastro-intestinal difficulties worth mentioning. Chest pain and cough yielded to simple measures. When the temperature was high it was dealt with by sponging, but the absence of respiratory embarrassment (as in lobar pneumonia) allowed these patients to be comfortable in spite of a high temperature.

There is no specific treatment, but several good reasons may be advanced for giving a sulphonamide when the lung lesion has been found.

1. The diagnosis of "atypical pneumonia" cannot be made with certainty in the first few days of illness even with *x*-ray evidence, and the administration of a sulphonamide for at least a few days is a valuable therapeutic test and an assurance against missing a pneumococcal pneumonia.

2. The "atypical" lesion is a debilitated area of tissue probably highly vulnerable to the flora of the upper respiratory tract, especially pneumococcus and streptococcus. It seems reasonable to hope that sulphonamides may inhibit secondary infection by these possible invaders.

3. It may be objected that sulphonamides may depress the already low leucocyte count. But it appears that the leucocyte count in these cases is around normal figures because this type of infection does not call forth a leucocyte response, since there is no indication that the count is low because of "depression" of the marrow. If this be so, it is not to be expected that sulphonamides will adversely affect the leucocytes to any extent. The findings in this series seem to indicate that sulphonamides from this point of view are harmless in the ordinary case.

On these grounds we gave to every case 2 g. of sulphapyridine or sulphathiazole when the diagnosis of a "pneumonia" was made, and continued with 1 g. every four hours for three or four days.

Association with Malaria

The majority of our cases were admitted during a period when there was a heavy incidence of malaria in the area. About one-third (30.3%) had the typical lung lesion in association with malaria. The presence of malaria did not, however, have any influence on the period of pyrexia due to the atypical pneumonia. In both groups (atypical pneumonia plus malaria, and atypical pneumonia alone) the average duration of pyrexia was eight days (Case 15).

If we had not been aware of the prevalence of atypical pneumonia many of the malaria-infected cases might from physical signs alone have been assumed to have merely associated bronchitis of malarial origin. Several cases had an acute onset resembling malaria, and the diagnosis became clear only as the illness progressed unaffected by quinine therapy (Case 49).

The fact that the presence of malaria, and antimalarial therapy, did not influence the duration of pyrexia seems to support the view that the association was fortuitous, although it is possible that a latent malaria might be activated by the onset of atypical pneumonia. Conversely, a population debilitated by malaria may well be more susceptible to this virus infection.

In North Africa we saw very many cases of malaria and only a handful of atypical pneumonia; but these malaria cases were largely fresh infections in healthy troops, whereas about 50% of the malaria infections seen in Italy were relapsed cases, often many times relapsed.

It would seem, therefore, to be true for primary atypical pneumonia, as according to Osler (Christian, 1942) it is for pneumococcal pneumonia, that its occurrence in association with malaria is fortuitous.

Radiological Findings

In common with other observations the *x*-ray findings in this series showed much diversity. In 56% the lesion was right-sided and there was a predilection for the middle and upper zones. In the lower zones the costophrenic angle area (Case 120) and less often the cardiophrenic area were the sites mainly affected. Lesions maximal at the hilum were usually on the right side.

In a few cases a whole lobe appeared to be involved, but in the large majority the lesion was small. The area of opacity in no case traversed more than one lobe, but in three cases a lesion was found at both bases. The appearances in these latter resembled the tracheobronchitis described by Kornblum and Reimann (1940). The opacities were never so dense as in pneumococcal pneumonia and usually showed some degree of mottling. Three showed an area of loss of translucency with marked reticulation at the hilum similar to the second type of Drew *et al.* (1943). The edges were indefinite except where bounded by a pleural line.

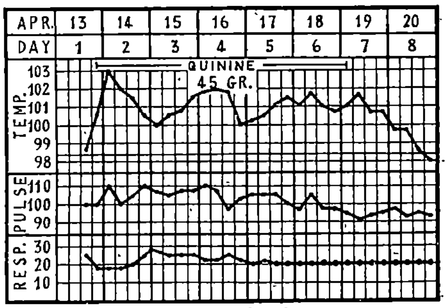

Fig. 1.—Case 15 Atypical pneumonia and benign tertian malaria.

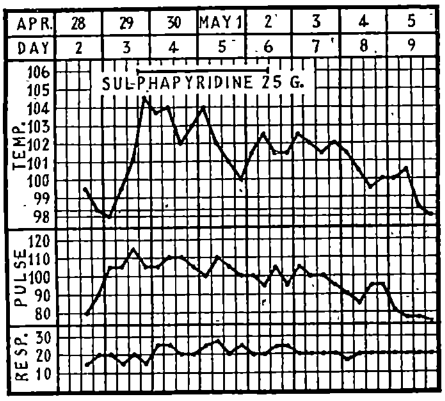

Fig. 2.—Case 49. Onset resembling malaria.

In one group the lesion was localized at the periphery but had no apparent connexion with the hilum; some of these were fan-shaped, with the apex towards the hilum (Case 118), but others were rounded or oval. In one the whole right supraclavicular region was involved. Where the lesion was fan-shaped one or more branches of a main bronchus were seen to be involved, as in the "partial pneumonias" described by Shanks, Kerley, and Twining (1938). In one case a lesion starting at the periphery was followed serially and was seen to spread towards the hilum.

The opacities usually persisted for some time, often several weeks, after the patient was afebrile, although in a small number resolution was complete before the patient left the hospital for the convalescent depot. In all those we were able to follow (34) the lung fields were clear in from four to six weeks after becoming afebrile, but frequently a thickening of the pleural line persisted. In nearly all cases the hilar shadow was enlarged on the side of the lesion only. In several cases with upper-zone lesions the *x*-ray appearances suggested tuberculosis, but serial films and the clinical course readily eliminated this diagnosis. Other writers state that lung abscess, carcinoma of the lung, unresolved lobar pneumonia, and bronchiectasis may simulate the appearances of atypical pneumonia; that difficulty did not arise in this series.

After the considerable experience afforded by this investigation it was found possible to make a fairly definite diagnosis by radiograph only; but, where there was doubt, correlation with the clinical findings clarified the issue.

Illustrative Cases

Case 2.—Pte. A., aged 20, was admitted on May 7 with a history of two days' headache and aching in the back. He shivered at the onset, and since then had been perspiring. He complained of loss of appetite and slight nausea, and had a little dry cough. There was no past history of malaria. On admission he was flushed and looked "toxic." No physical signs were detected in the chest. Temperature 101.8° F., pulse 100, respirations normal. Blood smears for malaria were negative. Two days later he complained of a tight feeling across the chest, and sticky rales were heard over the right upper lobe anteriorly. Next day a small crop of petechiae appeared on the chest and back. The white cell count on May 9 was 5,500 per c.mm. (polymorphs 64%, lymphocytes 27%, eosinophils 1%, mononuclears 8%). Some mucoid sputum obtained on the same day showed a few pneumococci, pneumobacilli, and non-haemolytic streptococci. The fever continued for six days and fell by lysis. Radiography showed infiltration extending from the right upper hilum to the right apex. This case was one of five admitted from the same unit; they were probably infected on the same day.

Case 15.—Pte. B., aged 20, had been over-seas for nine months, but had previously been well. His illness began on April 13 with the gradual onset of headache. He had no shivering, cough, or sputum. His temperature rose to 101.5° F.; pulse 90. Blood smears were positive for B.T. malaria, and he was given full doses of quinine. Next day his temperature was 103° F., and a harsh breath sound with a few crepitations was noted over the right middle lobe. Radiographs showed an area of infiltration, chiefly at the periphery of the right midzone and bounded below by the right middle pleural line. His temperature persisted around 102° F. for seven days, terminating by lysis on the eighth day. A follow-up radiograph on May 6 showed no abnormality.

Case 16.—L/Cpl. C., aged 25, was admitted on April 28. Four days previously he had a sudden onset of headache and backache accompanied by a rigor. On the morning of the 25th he wakened with a stabbing pain in the left back on breathing or bending. On the 27th a blood smear showed B.T. malaria, and quinine in full doses was given. On the 29th radiographs showed a small opacity in the left midzone, chiefly peripheral. On the 25th his temperature was 105° F. and pulse 100; thereafter he ran a sharp fever, uninfluenced by quinine, for six days. The white-cell count was 9,650. A repeat radiograph on May 12 showed clear lung fields. In this case there were no physical signs and no sputum throughout the illness.

Case 28.—Cpl. D., aged 22, was admitted on April 25 complaining of headache and of shivering for two days. Next day blood smears showed B.T. malaria, but examination of the chest was negative. On the 27th he produced some rusty sputum, and radiographs showed a fan-shaped patch of consolidation extending from the right upper hilum and bounded below by the right middle pleural line. The white blood count was 5,650 per c.mm. (polymorphs 64%, lymphocytes 30%, monocytes 5%, eosinophils 1%). The sputum contained many pneumococci, with streptococci and Friedländer's pneumobacilli. He ran a moderate temperature (100° to 101° F.) for eight days, and had a rapid convalescence.

Case 49.—Pte. E., aged 29, was admitted on April 29 with a history of sudden onset of headache, shivering, general aching pains, and slight cough, of 12 hours' duration. Blood smears for malaria were negative. On admission he had some small rales in both midzones, and next day a soft tubular breath sound was heard in the right lower zone anteriorly. Radiographs showed a band of consolidation extending from the hilum to the periphery and situated on the diaphragm. The white cell count was 13,600. There was no sputum throughout the illness, and he ran an intermittent high fever swinging between 100° and 104° F. for eight days, uninfluenced by full doses of sulphapyridine. Blood culture was negative. Convalescence was disturbed by the onset of a mild dysentery (Schmitz), but otherwise he made a rapid recovery.

Case 66.—Gnr. F., aged 22, was admitted on April 22 with a history of sudden severe headache, shivering, and backache two days previously. Blood smears for malaria were negative. During the first five days no physical signs were detected and he was treated for malaria, but on the 28th scattered rhonchi were heard over the right upper chest and, later, crepitations were heard at the inner end of the fifth right interspace. The white cell count was 5,800 per c.mm. (polymorphs 68%, lymphocytes 25%, monocytes 7%). Radiographs showed a small patch of consolidation in the right inner subclavicular region. He had an intermittent high fever for eight days, swinging between 100° and 103° F.

Case 68.—L/Sgt. G., aged 25, was admitted on April 28. For three days he had felt unwell with slight headache, anorexia, and backache. He had a slight cough but no sputum or chest pain. On admission his temperature was 102° F. and pulse 95. On the 30th he had a rigor, and blood smears showed B.T. malaria. On the same day crepitations were heard over the left upper zone anteriorly and radiographs showed a fan-shaped area of consolidation extending outwards from the left upper hilum to the outer subclavicular region. The white cell count was 3,300. There was no sputum throughout the illness. He had eight days' mild pyrexia, and three weeks after the onset radiographs showed only a little residual striation.

Case 113.—L/Cpl. H., aged 21, was admitted on Aug. 16 complaining of headache, dyspnoea, and general malaise. He also had pain in the right chest anteriorly on respiration. Three days after admission he had a small haemoptysis, but no physical signs were detectable till the following day, when crepitations with distant tubular breathing were heard at the right base and radiographs showed an oval consolidation situated on the diaphragm, which was slightly elevated. The white-cell count was 5,650 per c.mm. On admission his temperature was 100° F., but on the two succeeding days it reached 103° F., and settled by lysis on the sixth day. The pulse was never more than 100 and respirations 22. Culture of the sputum showed streptococci, pneumococci, and *M. catarrhalis.* A radiograph four weeks after the onset showed only a slight residual opacity.

Case 118.—Gdsmn. I., aged 22, was admitted on Sept. 25 with a history of a few hours' headache and shivering. His temperature on admission was 104° F. and pulse 110. Blood smears were negative for malaria. On the 27th no physical signs were detected, but radiographs showed a fan-shaped area of consolidation in the left upper zone, chiefly peripheral. The left hilar glands were notably enlarged. The white cell count was 5,200 (polymorphs 55%, lymphocytes 40%, monocytes 4%, eosinophils 1%). He had no sputum till four days after the onset, when there was a slight haemoptysis. He had a high intermittent fever (100° to 104° F.) for nine days, but made a rapid convalescence.

Case 120.—Dvr. J., aged 37, was admitted on Sept. 23 complaining of headache, shivering, and backache. He had a slight cough with a little mucoid sputum, and complained of pain in the left lower chest anteriorly. A few coarse crepitations were heard in this area, and radiographs showed a fan-shaped opacity in the left lower zone of medium density, extending outwards from the lower hilum and leaving the costophrenic angle free. The white cell count was 5,000 per c.mm. (polymorphs 61%, lymphocytes 37%, monocytes 2%). Blood culture was negative. Temperature on admission was 101° F.; thereafter he ran a high intermittent fever, with frequent peaks of 103° F., for nine days. Radiographs three weeks after the fever subsided showed that the lesion was rapidly resolving.

Discussion

During some months of the Italian campaign atypical pneumonia was an important cause of long-term sickness. As compared with other reports available to us, our cases ran a much more acute course, as evidenced by the high temperature maintained with small intermissions, but complications were absent and there was no morbidity. Our evidence supports the view that the disease is of virus origin, and the similarity of the clinical and radiological pictures suggests that in this series the same virus was responsible. There was no evidence of association with other known virus diseases. It is notable that diseases presumably due to a virus—infective hepatitis, varicella, poliomyelitis, and atypical pneumonia—have occupied a pre-eminent place as causes of long-term sickness in this campaign. This is testimony to the fact that in the Second World War the bacterial diseases have been largely under control, thanks to sulphonamides and the various prophylactic measures. Apart from typhus, the answer to most of the virus diseases is still awaited.

In many cases the severity of the illness was in marked contrast to the small area of lung involved. This suggests an analogy with poliomyelitis, in which the lesion may be very small even in fatal cases. But while a small local lesion is the rule in poliomyelitis, fatal cases occur, with widespread damage to the nervous tissue. Is it to be feared that atypical pneumonia also may produce extensive lesions, and will this prove to be the "influenzal pneumonia" of 1918 and 1929? Just as in severe cases of poliomyelitis acute haemorrhagic reaction may occur, so in atypical pneumonia frank bleeding from the irritated lung tissue is not infrequent, unaccompanied by the bacteria-laden mucus seen in pneumococcal pneumonia.

In view of the frequent association of malaria and atypical pneumonia in this series we recommend that cases of malaria which fail to respond to quinine should have a thorough clinical and radiological examination to exclude the association. It has been our practice in these cases to continue antimalarial treatment with quinine only when the atypical lesion has been discovered; for, as we have stated above, every patient in whom the pneumonia was diagnosed was given sulphapyridine or sulphathiazole, and it has been our experience that a sulphonamide and mepacrine together may not be well tolerated. The combined use of a sulphonamide and quinine, on the other hand, causes no disturbance.

Summary

Cases of primary atypical pneumonia to the number of 112 were admitted to a military hospital in Italy during the spring of 1944. For some weeks the incidence reached epidemic proportions.

Most of the cases had an acute onset and ran a high intermittent fever for an average of eight days. In other respects the clinical findings were similar to those in recent British and American reports.

There were no complications and no morbidity, but there was considerable debility, requiring four to six weeks' convalescence, so that the majority of these men were off duty for a total of about eight weeks.

One-third of the cases had a benign tertian malaria infection in addition to atypical pneumonia. There was no evidence that the association was other than fortuitous in a population among whom malaria was prevalent.

Sulphathiazole and sulphapyridine had no effect on the course of the illness, but we ascribe the absence of complications and secondary fevers to their routine use. There was no indication that they had any toxic effect on the polymorphonuclear leucocytes, and when used in combination with full doses of quinine, in the malaria cases, no adverse effect was noted.

We wish to thank Major W. Stewart for his assistance with the bacteriological examinations; S/Sgt. Maitland for his work with the records; and Col. R. I. Poston, T.D., for his co-operative encouragement.

INCIDENCE OF PUERPERAL AND LACTATIONAL MASTITIS IN AN INDUSTRIAL TOWN OF SOME 43,000 INHABITANTS

BY

A. A. FULTON, M.D., D.P.H.

Maternity and Infant Welfare Medical Officer, Corporation of Dundee

It is very difficult to estimate the true incidence of mastitis, as most statistics come from hospitals and cases occurring in domiciliary midwifery practice are not included. In addition, information is not as a rule available to the hospital staff as regards the occurrence of mastitis in patients after they have been discharged from maternity hospitals—usually not later than, and often before, the fourteenth day of the puerperium. Hospital statistics thus tend to underestimate the number of cases.

Moon and Gilbert (1935) state that the frequency of puerperal infections of the breast is probably underestimated and too little notice is taken of the associated morbidity, the chief reasons for this being that (1) patients pass to surgical care other than that responsible for delivery, and (2) there is practically no mortality due to mastitis. Waller (1938) supports this view, and is sure that many lying-in institutions underrate the risk of breast infections through not hearing of the results. Chatillon (1941) says that statistics found in the literature, although valid for any particular institution, give only a very imperfect idea of the real incidence of mastitis because of lack of information as to what happens to women after discharge from hospital or to those delivered at home. Macpherson (1943) also holds this opinion, and may be quoted: "Infection in the puerperal breast, however, has received less attention than its frequency and ill effects upon the mother merit, possibly because most cases begin about the time of the patient's discharge from institutional care, after a hitherto apparently normal puerperium." Rubeska is quoted in Williams's (1941) *Obstetrics* as finding a frequency of 0.54 to 4.1% in the various German clinics, while Waller (1938) found that out of 163 patients attending his clinic, and all delivered in one hospital, 11 (6.7%) developed suppurative mastitis. Chatillon (1941) estimates that the incidence has fallen during the past 40 to 50 years from 5–15% to 0.5–1.5%. Gilbert (1941) states that 3% in a series of 100 cases had recurrent mastitis—"which is higher than the usual incidence"; and Robinson (1943), in a series of 1,100 cases of failing lactation, found that 33 (3%) gave a history of breast abscess. It may be noted that most writers estimate the maximum frequency at the present time to be not more than 3%, and that the author who records the highest incidence (6.7%) obtained his statistics from a child welfare clinic.

In view of the meagre information available, apart from hospital statistics, about the incidence of mastitis it was thought that an inquiry into the relevant conditions in a circumscribed area might shed some light on the problem.

The Investigation

The area concerned is an industrial town in Scotland with a population of roughly 43,000, and has a municipal maternity hospital with 30 beds. In order to ascertain the actual frequency of mastitis a system of "unofficial" notification was initiated. Each health visitor was asked to notify, using a standard form of notification, all cases of puerperal or lactational mastitis occurring in her district. This did not give an absolutely complete incidence for the period under review, as almost certainly some cases were missed, but any inaccuracy must have been on the side of underestimation.

Criterion.—Definite evidence of suppuration was the criterion adopted as to what constituted mastitis. Without such a standard it would have been difficult to exclude "breast flush" or simple engorgement; and, for the purpose of this survey, mastitis was considered to be present only when there was a history of spontaneous evacuation or incision of an abscess.

Period under Review.—The notification scheme was started in Dec., 1941, and cases known to have occurred in the later months of 1941 were included to cover the period from Sept. 1, 1941. Any case of mastitis occurring after Dec. 31, 1943, was excluded. The period under review was therefore two years and four months.

Incidence.—This has been taken to be the number of cases of suppurative mastitis occurring from Sept. 1, 1941, to Dec. 31, 1943, as a percentage of the total births. The incidence found may be slightly lower than the true one, as the notifications for the months of Sept., Oct., and Nov., 1941, were retrospective and depended on the memory of the health visitors. For this reason the incidence for each year is given separately.

During this period 156 cases of suppurative mastitis were notified—i.e., almost one in every ten recently parturient women in the town certainly suffered from breast abscess—while the following must also be taken into consideration: (1) Some cases may not have been reported, or may have been missed for some other reason; (2) patients who had mastitis which resolved without going on to abscess formation were not included. The real incidence of mastitis, including non-suppurative forms, must therefore have been higher than the figures given in Table I would suggest.

TABLE I

	Total Births	Mastitis Cases	Percentage
1/9/41 to 31/12/41	251	16	6·37
1942	737 } 1,500	77 } 140	10·45 } 9·33
1943	763	63	8·26
Totals	1,751	156	Mean, 8·91

Parity.—In the series of 156 cases of mastitis 92 (59%) were primiparae and 64 (41%) were multiparae (Table II). The proportion of primiparae to multiparae in all the burgh births during the period concerned is not available, but it is possible to give the proportion for the maternity hospital. It may be contended that a hospital proportion would not be truly representative, as in most maternity hospitals first confinements predominate. This contention does not apply to any great extent in the hospital concerned, as most confinements (over 90%) were booked cases, admitted strictly in order of application and not on account of any anticipated difficulty nor because of primiparity; less than 10% were emergency admissions. Of the total confinements in the maternity hospital from Sept. 1, 1941, to Dec. 31, 1943, 51% were of primiparae. The proportion of primiparae to the total births for the burgh was not likely to be greater, and therefore it will be seen that a slightly larger number of primiparae developed mastitis (59%) than might have been expected from the proportion of primiparous patients (51%) found in the local institution. The percentage of primiparae in this series was not so high as that found by Moon and Gilbert (1935) in the City of London Hospital (73%), and was more in agreement with Winckel's estimate (two-thirds were primiparae) as quoted in Williams's *Obstetrics* (1941).

TABLE II.—*Parity*

Hospital deliveries:		Mastitis cases (156):	
Primiparae	51·4%	Primiparae	92 (59%)
Multiparae	48·6%	Multiparae	64 (41%)

Place of Delivery.—Most authorities are agreed that mastitis is more common in institutions. Moon and Gilbert (1935) found a much smaller incidence of mastitis in their district patients, who were, broadly speaking, of the same social status and general health as the hospital patients; and they came to the conclusion that acute puerperal mastitis is essentially an institutional disease. Chatillon (1941) says that mastitis seems to occur more often in maternity institutions than in the patients delivered at home, and Waller (1938) also considers that the incidence of mastitis is much higher in women delivered in institutions. Although in the present investigation very few cases of mastitis actually occurred in the municipal maternity hospital, 121 of the 156 patients (77.6%) had been delivered in the hospital (Table III), the condition usually developing after the return of the mother to her own home. This figure is higher than was to be expected, as the percentage of all burgh births taking place in the hospital for the period under review was under 43 (45 for the past five years). To put it another way, 16% of women delivered in hospital developed mastitis, while only 3.5% of women delivered at home did so. There is a significant difference here, and these figures provide strong evidence in support of the view expressed by most writers that mammary infections occur more frequently in women who are delivered in maternity institutions. Although mastitis was found to be more common in primigravidae the high incidence in hospital patients would not be accounted for by this factor alone, as only approximately half the patients delivered in hospital were primiparous women.

TABLE III

	Hospital	Home	Total
Number of confinements	748 (42·7%)	1,003 (57·3%)	1,751
Number of mastitis cases	121 (77·6%)	35 (22·4%)	156
Percentage who developed mastitis	16·18	3·49	8·91

Time of Onset.—As records of the time of onset of mastitis usually come from maternity hospitals, and as hospital staffs may have no knowledge of cases occurring after the patients have been discharged from hospital, the figures may exaggerate the earliness of its appearance. According to Williams's *Obstetrics* (1941) the symptoms are rarely seen before the end of the first week of the puerperium, and as a rule not until considerably later. Moon and Gilbert (1935) found that the average time of onset in a hospital series was the eleventh day of the puerperium, varying from the fourth to the twenty-fourth day. The exact date of onset was known in 93 of their patients, and in 80 (86%) it occurred before the end of the second week. According to DeLee (1938) the parenchymatous (most common) type seldom begins before the seventh day, and most often occurs from the tenth to the twentieth day. Kenny (1941) says that the symptoms usually appear late in the puerperium, often in the third week or later, while Macpherson (1943) found that 15 out of 26 cases (57%) occurred within one month of parturition. The authors of *Queen Charlotte's Text Book of Obstetrics* (1943) state that mastitis usually arises during the third week of the puerperium. Waller (1943) considers that 90% of acute abscesses of the breast occur within the first month after delivery. In the present series, in only 16 of the 156 cases (Table IV) did the first symptoms appear before the end of the second week, and in only four during the period normally spent in hospital. The highest weekly incidence was in the third week after delivery, and the latest time recorded was when the infant was 5 months old (two cases). Only 16 (10.3%) began before the end of the second week. This may be compared with the percentage of 86 given by Moon and Gilbert (1935); but their statistics related to a hospital series. The time of onset in our series was more in agreement with the views of DeLee (1938)—one-third of the cases occurring from the tenth to the twentieth day—and of the authors of *Queen Charlotte's Text Book of Obstetrics*. It should be noted, however, that, although the highest weekly incidence was in the third week, 45% of the cases occurred after the end of the fourth week.

TABLE IV

Discussion

The incidence of mastitis (8.91%) found as a result of this investigation is much higher than is generally believed to be the case. It can be argued that the town concerned had a larger number of breast abscesses than other areas; but this argument would be difficult to substantiate, because comparable figures for other areas are not generally available. Most statistics are gleaned from hospital records, and these of necessity include only cases occurring early in the puerperium and in women delivered under the aegis of the hospital—intern or extern. They do not include cases arising after discharge from hospital or those of women delivered at home by the family practitioner or midwife. Chatillon (1941) admits this difficulty, and casts doubt on the value of low statistics from hospitals. He says: "We know by experience that a number of mammary infections begin only after the patient leaves hospital." Published figures probably, indeed almost certainly, underestimate for this reason. The incidence reported from other areas would no doubt be much lower than that found in this investigation, but it should be noted that if the investigation had not been carried out the incidence for the burgh as obtained from hospital statistics would have been much lower. The number of cases actually occurring in the maternity hospital and known to the staff of that institution was very small. Reference to Table IV shows that in only five instances did the onset occur before the tenth day of the puerperium (the usual time of discharge from the hospital), and only 16 cases (10.3% of the total) occurred before the end of the second week. The one other likely source of information was the general hospital of the town, and it was found that only 58 of the 156 cases had been treated in that institution. The others, apart from those in whom spontaneous evacuation had occurred, had had incision done either in their own homes or in hospitals outside the burgh. The claim can therefore be made that it was only because of this special investigation that the high incidence was brought to light.

The incidence may have been still greater than the figures given in Table I would suggest, as it is highly probable that even with the aid of the notification scheme some cases were missed and cases of non-suppurative mastitis were excluded. It is significant that when, for the purposes of another inquiry, some 250 women in the same town were carefully followed up for a period of six months after delivery, the incidence among them was even higher—viz., 25.1%—and a further 5.4% had a history of mastitis which subsided without abscess formation. It may be submitted not only that the compilers of hospital statistics underestimate the frequency because they do not know about cases occurring outside, but that notification under a scheme such as that instituted for this investigation also underestimates, although not to the same extent, because of "missed" cases.

To account for the large number of cases of mastitis occurring during the period under review the possibility of an epidemic must be considered. It is of interest to note that the maternity hospital was closed at the beginning of 1943 because of an outbreak of post-partum pyrexia and other signs of infection. On the other hand, the incidence of mastitis during this period did not show any unusual increase, and, after a short period of closure followed by more strict limitation of admissions, the maternity hospital had no further trouble. It should also be noted that the incidence of other infections in the burgh did not show any abnormal rise during 1942 and 1943. If the high incidence found was due to the investigation coinciding with an epidemic period it would seem that the epidemic was of considerable duration, and the matter can be cleared up only by further observations.

Another fact which emerged as a result of the investigation was that there was a much higher incidence of mastitis among women who had been delivered in hospital. It should be pointed out that only one hospital was concerned, and it is possible that some factor applicable to that one institution may have been partly responsible; for instance, owing to excessive demands on its accommodation the hospital was often overcrowded. There is no doubt that this high incidence among hospital patients merits deep consideration in view of the increasing tendency for confinements to take place in institutions. Probably the most important factors responsible for the undue prevalence among hospital patients are as follows:

1. *The Presence of Micro-organisms in Cases of Infection, in "Carriers" (Patients, Staff, and Visitors), in Dust, etc., to Which the Newly Delivered Woman has Not Acquired an Immunity.*—At the present time "black-out" conditions and deficient ventilation probably increase the importance of this factor, and, although the same "black-out" conditions exist in the home, they may not be so dangerous, owing to the patient being more resistant to any micro-organisms present.

2. *The Possibility that in Overcrowded Nursery Conditions the Infant Acquires Micro-organisms which are Later Transferred to the Mother.*—Henderson (1943) has shown that there is a high incidence of neonatal infection in maternity hospitals, that *Staph. aureus* is the commonest cause of such infection, and that staphylococcal conjunctivitis is much the commonest staphylococcal lesion. He considers that the causes of the high incidence are overcrowding of nurseries, absence of barrier nursing precautions, and inadequacy of nursing staff. Benians (1943) found in a maternity hospital that a high proportion of infants and people of all ages carry *Staph. aureus* in the anterior nares; almost 100% of infants in the nurseries of the hospital were nasal carriers at the age of 10 days, and the carrier rate among the nurses varied from 25 to 85%. In such conditions, especially when overcrowding of the nursery coexists, it seems to be extremely likely that an infant may leave the maternity hospital harbouring in the eyes, nose, or skin a strain of *Staph. aureus* to which the mother is not inured; the transference of these organisms to the breast of the mother during suckling would be almost unavoidable.

In order to minimize the risks of infection it is very necessary that in maternity hospitals or units attention should be directed to the provision of adequate bed-spacing (the Medical Research Council Subcommittee (1944) recommends that the distance between bed centres should be not less than 12 ft.), proper ventilation, avoidance of overcrowding, and the desirability of cubicle nursing for both mothers and infants. It is also advisable that there should be ample window space, as Garrod (1944) has shown the bactericidal effect of light—even diffuse daylight; while van den Ende and his co-workers (1940, 1941a, 1941b, and 1941c) have demonstrated that oiling of floors and bedclothes reduces the number of dust-borne bacteria in a ward.

3. *The Tendency to Overcrowd Institutions.*—This may act in two ways—by increasing the chances of infection, and by reducing the time available for carrying out adequate prophylactic measures and for careful supervision of breast-feeding.

4. *The Rigid Hospital Routine of Feeding, with Unduly Long Intervals (Usually Four Hours) Between Feeds, thus Encouraging Stasis.*—This is probably an argument in favour of three-hourly feeding in the early days and also for feeding from both breasts at each feed. Moreover, there is the strict adherence to a time-table, so that the infant is kept for a fixed time at the breast, whether or not he is getting milk, thus tending to cause trauma of the nipple. Admittedly, more frequent feeding and more careful supervision during feeds would require a larger staff than most institutions possess at present.

5. *Malnourishment Predisposing to Infection.*—A further possibility to be considered is that the woman who is delivered in hospital belongs to a special type, perhaps of a poorer class and therefore more likely to be undernourished. Statistical information on this point is not available, but the impression is that the hospital patients in this series were representative of the population as a whole. Against this hypothesis is the fact that the results of this investigation showed that mastitis did not occur more often in women of the lower-income class.

To account for the fact that in this series most cases began after leaving hospital is difficult. It may be that so long as the patient is under supervision and strict precautions are being taken to prevent the entry of micro-organisms—such as by covering the nipple between feeds—the infection can be warded off. This prophylactic technique may, however, break down when the patient returns home, and infection may then occur. This would not explain why infection occurs less often in women delivered in their own homes, where, presumably, the same breakdown in technique is as likely to happen. Other possible explanations are a long incubation period for the infection acquired in hospital, infection of the mother by her infant after discharge from hospital, or that recently parturient women are discharged from hospital before the time of greatest susceptibility.

The maximum incidence occurred during the third week of the puerperium, and there would appear to be a strong argument in favour of retaining patients in maternity hospitals for a longer period than is the present custom or than is possible with the accommodation available. Women are discharged on the tenth day of the puerperium—or even earlier when there is a demand for beds—before lactation is sufficiently well established and at a period when great difficulty with the process is often experienced. At such a time, and before the mother has fully recovered from the confinement, the added strain and worry of going home to cope with household duties and a new infant, combined with lack of time to carry out the general routine of antisepsis learned in the hospital, may perhaps tip the balance and precipitate the onset of an infective process. It may seem inconsistent to point out that mastitis occurs much more often in women delivered in hospital and at the same time advocate that mothers should be kept for longer periods in hospital, but, once the mother is in hospital, there does not seem to be much to be said for discharging her before she is fully recovered in health and the process of lactation firmly established and secure.

Although the highest weekly incidence was in the third week of the puerperium, 45% of the cases occurred after the end of the fourth week. Cases occurring as late as this may well be missed by the compilers of hospital statistics having no cognizance of the results after the patients have returned to their homes, and this would apply even if the stay in hospital were extended beyond the present customary period.

Summary

Attention is drawn to the fact that most statistics relating to the incidence of acute mastitis are probably misleading and err on the side of underestimation.

An attempt to get some information regarding the true position in an industrial town of 43,000 inhabitants revealed an incidence much higher than is generally accepted. From information received under a notification scheme it was found that over a period of 28 months 156 women developed suppurative mastitis, giving an incidence of nearly 9%. It is suggested that any discrepancy between these figures and those published from other areas is due to the fact that the latter relate only to cases occurring in hospitals and early in the puerperium.

As comparable figures for previous years are not available there is no proof that the incidence has increased.

As a predisposing factor it was found that the place of delivery played an important part. Breast abscesses occurred in 16% of the women delivered in hospital and in only 3.5% of those delivered at home. While less than half the burgh births occurred in hospital, 78% of the notified cases had been delivered in hospital.

The onset occurred most commonly in the third week of the puerperium, but in 45% of the cases the first symptoms did not appear until after the fourth week of the puerperium.

A FURTHER CASE OF PARANOID PSYCHOSIS SUCCESSFULLY TREATED BY ADRENALECTOMY

BY

CLIFFORD ALLEN, M.D., M.R.C.P., D.P.M.
Psychiatrist to the Dreadnought Hospital

AND

L. R. BROSTER, D.M., M.Ch., F.R.C.S.
Surgeon to Charing Cross Hospital

A special study of adrenal disease has been made at Charing Cross Hospital since one of us (L. R. B.) performed an adrenalectomy on a case of sexual precocity over 15 years ago. In 1933 Broster and Vines published a study of ten women suffering from virilism and showed a differential staining reaction demonstrating differences in the cortical tissue of normal and sexually abnormal individuals of both sexes. About this time it was noticed that women suffering from virilism were often abnormal—undersexed or homosexual, sometimes psychotic. The cases operated on, and new cases, were studied psychologically. These were published in full in Broster's *Adrenal Cortex and Intersexuality* in 1938. This work attracted the attention of Dr. R. D. Gillespie, who discovered a woman suffering from a severe schizophrenic paranoid psychosis combined with adrenogenital virilism. He was kind enough to send her to Charing Cross Hospital, and a study was made on the effect on her psychosis of removal of one of her adrenals. The result was a complete cure, which was published in full (Allen *et al.*, 1939). The woman showed a prepsychotic personality of schizoid, " odd-man-out " type. There was a previous history of telegraphist's cramp and exophthalmic goitre. She noticed hirsutism at 14, which spread by the time she was 18. When seen at 34 she was very hairy, and for the past six years had thought she smelt. This hallucination had increased, and she finally became so psychotic that she believed people were talking about her and certification was considered. An adrenalectomy was performed, and 12 days after it she had lost her hallucinations and had become heterosexually attached to her dresser, who had been kind and patient with her. Three weeks after the adrenalectomy she became confused for a few hours, but this passed away, and she has never had a recurrence. She has returned to her position in the Post Office (from which she had been discharged and pensioned) and has continued to work there happily ever since.

We are fortunate in being able to present another similar case.

Case Notes

The patient comes from healthy Jewish stock. The father and mother are alive and well. One sister, aged 22, is a little hirsute, and a brother, aged 24, very hairy. There is no family history of neurosis or psychosis.

Personal History.—She is a good-looking brunette Jewess. Her birth was normal and she developed normally until 2 years old, when she had an attack of meningococcal meningitis in which she was unconscious and showed spinal rigidity, necessitating treatment in hospital for six weeks. She recovered, and started school at a normal age. A tomboy, good at games but below average at her lessons, her schooling was uneventful. She developed a facial tic on leaving school. There was strong masturbation guilt as a girl, and when she vomited after eating sardines, at the age of 12, she developed an obsessional fear of this recurring. When she left school she studied domestic science, disliked it, and transferred to a commercial college, which she enjoyed. She then entered her father's business and remained well till 1936 (aged 19), when she complained of pain in the right iliac fossa and a radiograph suggested appendicitis. The appendix was removed, but she still had abdominal pain. She had great anxiety over masturbation at this time, and became excited and upset, and could not sleep for a while. This passed off in time. She remained a little masculine in her interests: after leaving school she still played games, particularly cricket and hockey. Cosmetics were not used, and she smoked heavily after 21. Although she had one female friend, to whom she was attached, there was no overt homosexuality. At the age of 21 she went to her father and told him she had had two proposals from young men and did not know which to marry. Her father told her she must decide for herself, and she finally married a young man who worked in her father's business and who eventually became a partner. During her engagement she had a period of general restlessness and was depressed for a time. The phobia of vomiting increased and was accompanied by marked claustrophobia, with feelings of nausea, dizziness, and panic. These symptoms passed away before her marriage. This was successful, but there was no real sexual happiness, and she complained of having little or no orgasm.

There was no further illness until she went to a dance in Dec., 1940. This was at a Manchester hospital. There was an air raid, and the shelter in which they took cover received a direct hit from a bomb, killing a woman next to her. She was found running down a corridor, without her shoes, calling for her husband in a hysterical state. She was put in bed for three weeks, apparently recovered, and remained well till the autumn of 1941, when her previous symptoms returned with greater intensity and she complained of giddiness, inability to concentrate, obsessional fears of sirens, anxiety lest there should be further raids, abdominal discomfort, and sexual dissatisfaction. She insisted that something was wrong with her abdomen. On Feb. 4, 1942, she saw Dr. Henry Cohen, who diagnosed an obsessional psychoneurosis and recommended psychotherapy. He thought that her personality was schizoid, but found no psychosis present. As a result she was sent to the Cassel Hospital on Feb. 24, 1942. Unfortunately when she arrived she was inaccessible with blocking of thought, staring into space with inability to concentrate. Psychotherapy was impossible, so she was given electrical convulsive therapy (twice weekly—seven shocks in all), bellergal, and paraldehyde. She was discharged, with a diagnosis of a depressive state with schizoid and hysterical features, because of her suicidal impulses. Psychotherapy was then started by Dr. Cross of Manchester. She was accessible when treatment began—April 13, 1942—but rapidly became depressed, sleepless, and self-accusative. Treatment was abandoned on Aug. 4, as psychotherapy was impossible. She then saw Dr. Barton Hall, at Liverpool, who diagnosed katatonic schizophrenia and advised treatment at Crichton Royal Infirmary. She was transferred there in October. She had further electrical convulsive therapy—six convulsions—and insulin. She wore trousers and smoked heavily during her stay. She was attracted to another female patient, and attempted to caress, and make physical advances to, her. She was restless, complaining, vicious, overactive, and interfering: she tried to reorganize the wards. She left on Dec. 5, but took such a long time packing her clothes that she and her husband missed the train and were forced to spend the night at a hotel in Dumfries. They attended a dance in the evening, but she misbehaved and was noisy and obstreperous. It was with difficulty she was persuaded to return to their room. Sexual relations took place that night. When she arrived home she continued to behave badly, and was more or less uncontrollable; she destroyed all her underclothes, threw away the household goods, made a violent homosexual attack on a nurse in charge of her, refused to go to bed, and was almost impossible to manage. She again saw Dr. Barton Hall, who diagnosed her as a typical katatonic schizophrenic with flexibilitas cerea and attacks of katatonic excitement. She was therefore transferred back to Crichton Royal Infirmary, where she had further electrical convulsive therapy (six shocks). She improved, but still remained katatonic, hallucinated, and solitary. She was given further insulin therapy without effect.

In Feb., 1943, it was noticed that she had amenorrhoea, and an Aschheim-Zondek test was performed on the advice of Mr. Dewar, the visiting gynaecologist. This was positive, so it was decided, in view of the deterioration in the psychosis, that the pregnancy should be terminated. This was done on March 8, and an 8-weeks foetus was removed. She was still very psychotic and hallucinated, muttering to herself, so she was given further insulin therapy. She had 65 insulin comas between April, 1942, and July, 1943, but remained facile and fatuous, and behaved as a naughty child.

It was then noticed that she was becoming hirsute, and endocrine dysphasia was suspected. Mr. Dewar suggested that it was of pituitary or adrenal origin. Her pituitary was investigated but found normal. Dr. Hain, of the Animal School of Genetics of Edinburgh, tested her urine and showed pregnanediol in the merest trace. The ketosteroid excretion at various dates was: May 15, 1943, 21 mg. a day; July 29, 1943, 46 mg.; Sept. 28, 1943, 24 mg.; Jan. 18, 1944, 17 mg. (Average 27 mg. a day.)

Mr. Dewar advised 5 mg. of progesterone three times weekly. The patient improved during Sept., Oct., and early Nov., 1943, but unfortunately relapsed later in November and became grossly deluded again. She attempted suicide by drinking petrol. The progesterone injections were continued without apparent effect, either physical or psychological. She tried to make a further homosexual attachment to another patient, but was separated from her. On Jan. 19, 1944, Dr. Wislicky, her private doctor, asked for her to be examined with a view to adrenalectomy, and this was kindly permitted by Dr. McCowan, the superintendent of Crichton Royal Infirmary, and by Dr. Meyer Gross, under whose care she was there. She was seen on Jan. 19.

Physical Examination.—She was a well-built woman of 26 years, dressed in a pullover and trousers. Her hands were stained with nicotine. Her cheeks had a high natural colour with thick down on them, as well as on the upper lip and chin. There was coarse, thick hair on her thighs and legs, but not so thick on the arms and forearms. There were tufts of hair on the dorsum of the toes but not on the backs of the fingers. The hair had a masculine distribution over the abdomen and some stretched up to the chest. The fat distribution was masculine in type; the buttocks were more masculine in shape than feminine, but this was not marked. She was strong, without the very developed musculature observed in these cases. No abnormality was detected in any system. Her nervous system was perfectly normal from the organic point of view. Her blood pressure was 120/80.

Psychological Examination.—She was accessible, co-operative, and behaved well while examined. She said she felt ill but properly orientated, and appreciated she was being examined to help her to recover. She stated that she was worried by airplanes, which gave her electric shocks when they flew over, and vaguely connected this with her wiry hair. She said spontaneously that she was hallucinated and heard "voices" saying obscene words to her. She often missed the thread of conversation, and this she explained as due to the "voices" distracting her attention. She had feelings of influence, and felt she knew also what people were thinking. She said she attempted suicide because she was Jewish and people hated the Jews, but had no antisemitic delusional symptoms. Her mood was gloomy but not depressed or anxious. She said her voice was more masculine, and she wore male clothes. She felt she was deteriorating and wished for treatment. Insomnia worried her. A diagnosis of schizophrenia in a woman suffering from adrenogenital virilism was made. She was transferred to Hampstead and examined there. She was extremely suspicious and confused, and stared absentmindedly into space. She spoke slowly and with hesitation. In view of her physical condition it was decided she was suitable for adrenalectomy. A laparotomy was performed on Feb. 21, 1944, and the left adrenal was found to be the larger of the two. The left ovary was fibrotic. A month later an adrenalectomy was performed. The pathologist reported that "the cortical cells showed the presence of a large amount of granular red staining material (ponceau-fuchsin stain)." A further specimen of urine taken two weeks after operation showed that the excretion of ketosteroids had dropped from 27 mg. to 7.2 mg. a day. Surgically this patient was typical of Group II virilism. Her hair could be pulled out easily, and in three months her period had settled down regularly to three to four days in a 28-day cycle.

Post-operative Findings.—The patient was re-examined on March 30, 1944. The improvement was striking. She stated she was thinking better and felt she would improve further. There was more insight. The hallucinations had gone, although she was still inclined to day-dream. She had lost her delusions and no longer felt "electric-shock" sensations when airplanes flew over: this was remarkable, as there were constant air raids at the time. She talked more freely and was less taciturn. She was more feminine and took more interest in her surroundings. Her mood was brighter and she welcomed visitors. She continued to improve. The daily steroid output fell from 30 mg. to 7.2 mg. She was well psychologically, although on April 6 she complained of some pain over the right iliac fossa and was passing jelly in her urine. This was investigated and found to be of no significance. (It should be noted that the previous case also had a short period of confusion three weeks after her adrenalectomy.) Her husband was seen at the time, and was very happy over the result. She complained that she had " no decent clothes to wear " and spent the remaining time in the nursing home going out with her husband, visiting cinemas, dancing, and improving her wardrobe. She worried over running a house and over the " points " system of rationing. In fact, her conversation was that of any intelligent woman suddenly faced with the difficulties of wartime life after years of isolation. She has been seen twice since her operation, and still maintains her recovery. On Nov. 2, 1944, she wrote to say that she was spending her time shopping, cooking, and housekeeping, and drove her husband's car when possible. The letter was that of a perfectly normal person—which indeed she now is.

It is of interest to note that this is the sixth case in which adrenogenital virilism has been combined with a psychosis, and the fourth in which the psychosis was schizophrenic in nature. The response to adrenalectomy was exactly similar in the previous case we were able to observe before and after operation. The fact that this patient was given the finest treatment (apart from adrenalectomy) suggests that these cases are unlikely to respond to ordinary therapy.

Summary

A further case of adrenogenital virilism combined with a paranoid psychosis is recorded.

These conditions occasionally arise together, and the occurrence of a syndrome, though of necessity a rare one, is possible.

Adrenalectomy appears to be successful in a certain number of cases.

As this condition does not seem to respond to other forms of treatment adrenalectomy should always be considered.

We are grateful to Dr. Wislicky of Manchester, Dr. P. K. McCowan, superintendent of Crichton Royal Hospital, and Dr. Meyer Gross for kindly allowing us to see this case, and for the use of notes and photographs; also to Dr. H. W. C. Vines, pathologist to Charing Cross Hospital, for allowing us to report his findings.

HYPERTRICHOSIS WITH MENTAL CHANGES

THE EFFECT OF ADRENALECTOMY

BY

RAYMOND GREENE, D.M., M.R.C.P.

A. SPENCER PATERSON, M.D., M.R.C.P.

AND

G. C. LAWRIE PILE, M.B., F.R.C.S.

Physician, Psychiatrist, and Surgeon, respectively, at Tindal House Emergency Hospital, Aylesbury

The following case of hypertrichosis associated with mental changes, which gradually resolved after adrenalectomy, may be considered worthy of record for its psychiatric interest.

A married woman aged 25 was admitted to hospital on Feb. 1, 1944, under Dr. V. E. Lloyd-Hart and referred to A. S. P. and to R. G. for investigation. She had always, according to her mother, been somewhat introspective, imagining herself to be more seriously ill than others believed her to be. She was married to a soldier, then in Italy, with whom her relations had not been altogether happy owing to his alcoholic habits, but this worry had been relieved from the time he had joined the Army over a year before. Her mother, with whom she lived, was an invalid with an irreducible hernia who suffered from hysterical fits. The patient's young son had severe asthma, which often disturbed her at nights. She remained well until March, 1943, when she had an attack of cough with pyrexia. From that time she began to complain, to a steadily increasing extent, of a roaring and buzzing in the ears, " pins and needles " all over, nausea and abdominal pain, sudden feelings of exhaustion during which she contemplated suicide, insomnia, and a feeling of extreme tenseness and tremulousness. During the five months before her admission all these symptoms became worse, and in addition she began to perspire excessively and offensively. Acne and an inordinate growth of hair made their appearance. Her complexion became sallow and her weight dropped from 9 st. 7 lb. to 8 st. 3 lb. Her breasts became smaller and her menstruation, which had always been somewhat irregular, became scantier and less frequent, appearing for two days at intervals of 24 to 45 days.

On examination she was found to be a thin, sallow dark-haired woman looking 10 years older than her age and with a permanent expression of discontent. There was an excessive growth of hair on the arms, forearms, back of the hands, thighs, legs, and face. The pubic hair was feminine in distribution but excessive. Acne was present on the face and back. The blood pressure was 145/85 and the pulse rate varied between 72 and 100. The breasts were flat and deficient in glandular tissue. Otherwise nothing abnormal was found on ordinary clinical examination. Psychiatric examination revealed a tense hypochondria rather than a true depression. The patient had had certain worries, as already described, but the resolution of some of these had not resulted in any improvement in the hypochondriacal state.

The following further investigations were performed. Glucose-tolerance test: Resting blood sugar 79 mg. per 100 c.cm.; after 50 g. of anhydrous dextrose, half-hourly values of 133, 143, 116, and 108 mg. per 100 c.cm. Blood count: Haemoglobin 110%, R.B.C. 6.2 millions, W.B.C. 7,000. Androgen excretion (Dr. Lloyd Warren): 21 mg. of 17-ketosteroids a day. Perirenal insufflation (R. G.) suggested slight enlargement of the left adrenal gland, but was not conclusive.

A diagnosis of adrenal virilism was made, but in view of the indefinite skiagram she was discharged and readmitted a month later. Perirenal insufflation then seemed to show an increase in size of the left adrenal—an appearance which was actually illusory. The 17-ketosteroids had increased to 33.8 mg. a day. Operation was therefore advised.

At operation on April 21, 1944, the abdomen was explored through a transverse incision extending from just above the umbilicus to the 10th left costal cartilage. After palpation of the pelvic organs had excluded any gross abnormality the peritoneum was closed and the left adrenal identified and removed extraperitoneally. The extraperitoneal removal was helped by high spinal analgesia and the use of diathermy; it was made very easy by the extreme thinness of the patient. The gland was macroscopically normal. The usual precautions against shock were instituted (eucortone before operation, intravenous saline, and repeated blood-sugar estimations for the first 48 hours after operation), but her post-operative condition never gave rise to any anxiety.

The preliminary perirenal insufflation had excluded an adrenal tumour on the right side, and it was therefore possible, by the use of a transverse incision, to combine the essential preliminary exploration of the abdomen with the removal of the affected adrenal. This saved the patient a second operation. Histological examination of the adrenal gland showed a positive reaction to the ponceau-fuchsin stain.

A few days after operation the limbs were shaved, but the hair on the face was allowed to remain. During the next few weeks it gradually disappeared. Two months after operation she looked much more youthful. There was no sign of further growth of hair in the shaven or unshaven areas. She was still rather tense and anxious, and complained, though with less insistence, of indigestion. The noises in the head were now intermittent and were increased by solitude, inertia, and worry. She had not menstruated since the operation.

Eleven months after the operation a remarkable change was found. She looked her age—10 years younger than before the operation. Her weight had risen to 8 st. 9½ lb. Her complexion was no longer sallow, but a normal pink and white. There was no acne or hypertrichosis, though she had not shaved or used a depilatory. Her habitual frown had given place to a ready smile. After three oestrogen withdrawal bleedings had been induced, regular menstruation had begun and had occurred for the last five months without any further treatment. The noises in the head were now absent for long periods and were only occasionally brought on by worry. She was no longer tense, and considered herself to be psychologically normal. Her parents said that she had ceased to be self-centred and that she no longer " played up " or talked about her ailments. They were most impressed by her youthful appearance. Her 17-ketosteroid excretion was now (April 27, 1945) 18.8 mg. a day.

Discussion

The association between adrenal virilism and mental change is discussed by Allen and Broster in their paper on page 696 of this issue. The case here described is of considerable psychiatric interest. The psychological changes preceded the external physical changes. When first seen the patient was drifting into a tense hypochondriacal state in which at times she wished for death. The removal of most of the real causes for her anxiety did not bring about her recovery. This state is notoriously difficult to influence by psychological means.

Only after operation was she set on the road to recovery. It is noteworthy that the insomnia, dyspepsia, and the morbid habit of magnifying the noises in her head did not disappear immediately after the operation but improved over a number of months concurrently with the remarkable change in her appearance. It seems reasonable to suppose that the rejuvenating effect of the operation enabled the patient gradually to emerge from her hypochondriacal state.

TREATMENT OF IMPETIGO

THE VIRTUES OF CALAMINE LINIMENT AND SOME MINOR DRAWBACKS OF LOCAL SULPHONAMIDE THERAPY

BY
MARY S. SMITH, M.D.
Major, R.A.M.C.
AND
E. COLIN JONES, M.B.
Major, R.A.M.C.

(From a Military Skin Hospital)

No one with experience of treating impetigo can fail to have been impressed at some time or other by the disastrous effects of using a remedy to which the patient's skin happens to be intolerant. First of all there is the major disaster of sulphonamide sensitization, in which the unlucky patient, after weeks or months of treatment, finds himself sensitized, perhaps incurably, to exposure to ordinary daylight, not to mention half a dozen of the potential irritants of a chemical nature he may have encountered during his illness.

But we are not so much concerned with dangers that are well known as with the accidents of therapy that may conceal their nature under the guise of an intransigent malady that persists in getting worse in spite of our treatment, or that somehow just does not get well. Such events are much more common than may be imagined. It is always well to remember the four things that a given local treatment can do: it can, of course, do nothing at all; it can make the disease better; it can make it worse; and it can prevent it from getting well.

It is the last possibility by which one is so often deceived. We therefore venture to draw attention to a mode of treatment which, incidentally, we claim to give results superior to all others in our own hands, but which also has the great virtue of avoiding the application to the skin of antiseptics or other substances capable of irritating it or giving rise to sensitization. Its main disadvantages are the extravagant use of dressings and the need for considerable skill and care in their application; but these are decisively outweighed by the reduction of the time spent in hospital, and the entire avoidance of disastrous sensitization phenomena.

The Calamine Liniment Method

Our method rests on six principles: (1) The free exposure of all parts to treatment—by shaving, if necessary. (2) The avoidance of trauma (apart from that occasioned by shaving). (3) Ensuring that the dressings are kept in close apposition with the affected parts, and that they remain moist. (4) That they are removed only for the few minutes necessary for shaving or re-dressing, and immediately reapplied. (5) That every outlying lesion is included in the treatment and that the dressing extends an inch or so beyond the affected area. (6) Finally, that the method of applying the remedy is altered as occasion demands—e.g., from compresses to smears—not the remedy itself.

Since each of these principles is of importance and neglect to observe any one may result in failure, we feel justified in entering into more detailed explanation of some of them.

Exposure of Affected Parts.—Ruthless shaving is, in our opinion, the key to success. On admission all hairy areas which are crusted are shaved, no matter how raw. To offer a little protection to the tender area, and to aid in softening the crusts, the parts are first anointed with lanette wax base; a lather of soap and water may or may not be used. No attempt should be made to save the hair of the scalp or eyebrows if involved. They should be thoroughly shaved, as even a small tuft of hair overlooked will delay cure. The eyebrows grow rapidly, and in the presence of persistent crusting it may be necessary to re-shave. Over the bearded region this should be done every second day.

Lanette Wax Base

Lanette wax	10 parts
Vaseline	10 ,,
Water	ad 60 ,,

Modified Calamine Liniment (to economize oil)

Adeps lanae	2½ oz.
Lanette wax	2½ ,,
Calamine	3½ ,,
Olive oil	20 ,,
Water	ad 80 ,,

Avoidance of Trauma.—To shave and to avoid trauma are apparently contradictory instructions. The damage caused by shaving is outweighed by the rapid healing which results from the closer contact secured for the dressing. Apart from shaving, no attempt is made to encourage the removal of crusts. Those crusts which do not separate readily and come away with the first dressing are not interfered with, as they seldom fail to do so with subsequent dressings, leaving a surface rapidly healing or healed.

Dressings.—For the dressing to be effective the closest contact is essential. Folds of gauze, four to eight layers thick, are completely saturated with calamine liniment and moulded on to the affected parts. Apposition in the natural folds is secured by packing and firm bandaging. The ear presents special difficulty. Several layers of gauze in the form of a tape are well saturated and tucked into all the natural folds and crannies of the ear. A similar dressing is made to encircle the ear to prevent the fissuring which so readily occurs at the upper and lower poles and in the retro-auricular fold. Unfortunately the ear dressing sometimes causes earache. To obviate this a dry plug of cotton-wool is inserted into the meatus and changed with each dressing. If the skin infection extends into the meatus the plug can be saturated with the liniment. To reach the deeper parts, otherwise inaccessible to dressing, a drop of cod-liver oil can be instilled. This relieves discomfort. An ear-cap of saturated gauze should be applied to keep the dressings in position. The response to this careful dressing is dramatic, and all crusting disappears in 24 to 48 hours. Subsequently the liniment can be simply smeared on without any dressing to cover it.

After discharge the patient is advised to wash or shave over a protective layer of lanette wax base or calamine liniment for a few days.

There still remain a few points on technique to be mentioned. First, the use of jaconet as a covering dressing. By retaining moisture, this economizes labour and material. Twice-daily treatment has sufficed, and fewer layers of gauze are required. Hot weather and the presence of acute inflammation are contraindications to the use of jaconet. It is essential at all times that the dressings remain moist; otherwise, by adhering, they may cause damage.

Pitfalls leading to failure arise from insufficient padding of the natural folds—e.g., fold of chin, angles of mouth, nasolabial folds, and bridge of the nose—and from bandaging that is not firm enough to keep the padding in position. If the angles of the mouth are involved it is an advantage to apply to the upper lip a dressing which is overlapped at the angles of the mouth by the firm lower-jaw bandage. The naso-labial folds should be treated in the same way as the folds of the ear—with a tape dressing. Bandaging must be firm, and to achieve this two half-masks, consisting of goggles and a four-tailed bandage for the chin, are preferable to one face-mask, which would tend to sag in places. The eyebrows also need particular care, and a specially thick firm dressing to ensure the rapid removal of all crusts. Liq. tinctor. applied twice daily to the eyelids will deal effectively with any lesions too close to the eye for bandaging.

The main points in the management of the case have now been dealt with. There is, however, one other item of supreme importance—that of not lightly changing treatment. One change is apt to lead to numberless others, until the medical officer and skin are both bewildered—the skin finally refusing to tolerate treatment.

Comparison with Sulphonamide Treatment

The method just described was elaborated by us towards the end of the period during which the local treatment of pyodermia with sulphonamides was fashionable, and we cannot dismiss the subject without further reference to that popular form of treatment. In a series of 643 cases, comprising 364 of impetigo and 279 of infective dermatitis, we recorded, with reference to the local treatment received before admission, the length of stay in hospital before the patient was fit for duty or for discharge into civilian life.

Of the cases of impetigo which had a general average stay in hospital of 14.5 days, 84 had been treated with sulphonamides for an average of 22 days; of the rest—some of which we ourselves treated with sulphonamides, some with calamine liniment, and some with other remedies—the figures were 11.4, 10.8, and 12.6 respectively. Of the cases of infective dermatitis, 63 which had been treated elsewhere with sulphonamides took 28.1 days on the average to get well, as compared with 18.6 days for the rest. It will be seen from these figures that the average duration of stay in hospital of the cases we ourselves treated with sulphonamide is scarcely longer than that of the cases treated with calamine liniment. Selection played a part in this. Mild cases for which expenditure of large quantities of liniment and dressing appeared extravagant, and cases of the types considered especially amenable, were treated with sulphonamides, while all the more severe ones had calamine liniment. Nevertheless, we feel it necessary to set out once more in tabular form the advantages and disadvantages of the two methods:

Local Sulphonamides	*Calamine Liniment*
1. Ease of application (as thick smears, twice daily)	1. Elaborate procedure requiring care and skill
2. Economy—no dressings required	2. Initially extravagant in material—saturated dressings, jaconet, bandages, etc., but smears only later
3. Aggravation of local condition encountered not infrequently	3. Aggravation rarely if ever encountered; almost foolproof
4. Risk of delaying response to subsequent treatment	4. No such risk; a favourable preparation for subsequent treatment
5. Experience required in choosing the type of case likely to respond straightforwardly to treatment	5. No such experience required
6. Limited safe period of use, 5–7 days; beyond that, increasing risk of sensitization	6. Unlimited safe period
7. Risk of later serious after-affects: (1) sensitization to light; (2) sensitization to sulphonamides	7. Safe treatment; no bad after-effects

Summary

Antiseptics are not necessary in the successful treatment of impetigo. The use of any of them—mercurials, dyes, sulphonamides, etc.—entails the risk of disastrous aggravation of the disease. Unsuccessful treatment with sulphonamides, quite apart from obvious sensitization phenomena, makes subsequent cure more difficult. A method of treatment with a simple calamine liniment is described and recommended for use in severe cases of all kinds of impetigo and infective dermatitis.

We are indebted to Lieut.-Col. Wilson for his interest and the suggestion of extending the application of calamine liniment to the external meatus in the presence of otitis externa; to Major Twiston Davies, command dermatological specialist, for his untiring help in preparing this paper; and to the nursing staff, especially Sister Joyce, who suggested the ruthless shaving.

The Malta Health Report for 1943 appears over the signature of Dr. A. V. Bernard, Chief Medical Officer. During the period under review there was a rapid and substantial improvement in the public health of Malta and Gozo. Although overcrowding was worse than ever and environmental sanitation far from perfect, the special attention paid to maternal and infant welfare work, the small incidence of infectious disease, and the use of sulphonamide drugs in treatment of respiratory and intestinal infections all helped in reduction of the death rate. Antidiphtheria inoculation brought down the mortality from this disease to the lowest for nineteen years. The slaughtering of many goats during the siege and pasteurization of milk resulted in a lower incidence of undulant fever than ever before. Only one case of indigenous malaria (benign tertian) was observed. War casualties were 5.7 per 1,000 of the population. An explosive outbreak of typhoid fever followed percolation from a bomb-damaged sewer into one of the main water reservoirs. Subsequently an Order was issued for compulsory inoculation. This is the last of a series of reports which deal with actual war conditions in Malta.

Medical Memoranda

Expulsion of Ectopic Foetus per Rectum

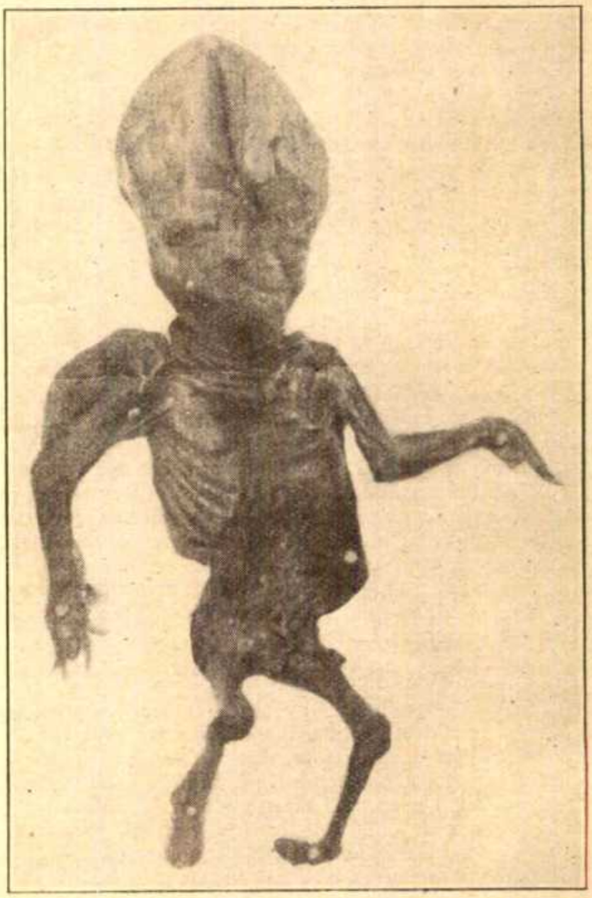
It is a rarity for a foetus to be expelled per rectum, and for this reason this case is being reported.

CASE REPORT

The patient, aged 28, came to the hospital complaining of acute abdominal pain, abdominal swelling, and obstinate constipation. Just before admission she had a severe uterine haemorrhage after a period of three months' amenorrhoea. With this bleeding there were vomiting and inguinal pain. Previously menstruation, which started in her fourteenth year, had always been regular. In this year she married and for ten years she remained sterile. Her husband died and she remarried.

On admission the temperature was normal and the pulse 90. The patient was pale. Abdominal examination revealed a hard mass rising out of the pelvis and reaching half-way to the umbilicus. Per vaginam the uterus was found to be anteflexed, and the fundus was felt one finger above the pubis. The portio vaginalis was conical and the cervix closed. The posterior fornix was distended by a hard mass separate from the uterus and filling the pouch of Douglas. Posterior colpotomy was performed, but no discharge followed this. Pelvic haematocele was diagnosed and the patient treated conservatively. For six days the temperature remained at 39° C. As there was no improvement operation was advised, but the patient refused and left hospital.

A fortnight later she returned complaining of rectal haemorrhage and stating that she had passed a foetus per rectum two days previously. The foetus (see photograph) was 9 cm. in length an mummified. On rectal examination a fistula could be felt, 3 cm in diameter, on the anterior wall about 7 to 8 cm. from the anus Through the fistula the finger entered the large sac of the haematocel There was a blood-stained blackish discharge. For 22 days th temperature varied between 37 and 38° C. At the end of this tim she was examined again. The uterus was deviated to the left, bu the left fornix was normal. On the right side there was a mas the size of a fist, attached to the pelvic wall. The patient made a uninterrupted recovery.



From the literature available there has been a similar typ of case reported (Binagh and Bardi, 1929), but the whole c the foetus was not expelled per rectum.

Reviews

ENDOCRINOLOGY OF WOMAN

Endocrinology of Woman. By E. C. Hamblen, M.D., F.A.C.S. (Pp. 571; illustrated. $8.00 or 58s.) Springfield: Charles C. Thomas; London: Baillière, Tindall and Cox. 1945.

The war, by slowing down research in sex endocrinology, has, as Prof. Hamblen points out, provided an opportunity for an appraisal of the results of the spate of experimental work of the pre-war years and for assessing the value of the various discoveries when applied to clinical medicine. This book, which he has written in place of a second edition of his previous work *Endocrine Gynecology*, takes full advantage of this opportunity and is an admirable survey of the field. There are many books on the subject, but this is one of the best. It differs from others in that it has a broader outlook and puts the reproductive system in its proper perspective, paying due attention to other systems and bodily processes, such as growth and metabolism, which are affected by hormonic processes. All the glands with an internal secretion—the pancreas, thyroid, thymus, parathyroids, pineal, in addition to the pituitary, gonad, and adrenal—are considered. Moreover the importance of the endocrine system is not overstated, nor the place and value of hormone therapy. Prof. Hamblen does not allow enthusiasm for his specialty to affect his clinical judgment, and how pleasing it is to find simple common-sense treatment of a non-endocrine nature recommended in place of more fanciful and expensive types of hormone therapy of questionable value. Theories without sound foundation, conflicting views, and unconfirmed findings are mostly omitted, so the book is essentially a practical one. References are made only to articles written in English. It is, as claimed, "streamlined," but it remains a moderately large book for the reason that it contains a wealth of detailed information, presented in well-ordered and attractive manner. There are few matters which fall within the orbit of its title to which reference is not made.

The book is divided into five sections. The first deals in turn with the various glands—their development, anatomy, histology, function, and interrelationships, with an account of the chemistry and actions of their hormones. Each chapter is introduced by an outline of the history of the main discoveries regarding each gland. The second part is concerned with sex differentiation and the behaviour of the endocrine system during intra-uterine life, childhood, maturity, and the development and retrogression of reproductive activity. The clinical investigation of both the adult and the child, special tests and diagnostic procedures, blood and urine chemistry occupy the third section, while the last two deal with functional diseases of the various glands and endocrine therapy respectively. Throughout there are good diagrams and illustrations, and most helpful tables showing differential diagnosis, hormone levels in body fluids, etc.

The book bears the imprint of a strong personality, which comes to the surface more particularly in the clinical sections. This gives it an impressive sincerity and honesty but has the disadvantage that some views and types of treatment, though generally accepted, are not described because they do not meet with the approval of the author. Thus all forms of androgen therapy for any condition in woman are only mentioned to be condemned. This attitude may prove correct, but it is doubtful whether the present state of knowledge justifies it. Again, there are few who would agree that the use of oestrogens for the suppression of lactation is unnecessary and that the older methods of a binder and purgation are equally efficient. But there are not many examples of this type which could be quoted, and to compensate for them is the fact that every form of treatment recommended has been used personally by the author.

Prof. Hamblen in his preface says the book is intended for undergraduates as well as the newly qualified, but that is to underrate its scholarship. It is more suited to the gynaecological specialist, who not only will find in it an easily assimilated summary of all that is of practical value in recent developments in the endocrine field but will also wish to keep it for reference when dealing with any unusual and difficult case. Even those who already possess a reference book of this type would do well to read it if only because of its well-balanced outlook and its critical and rational approach to the subject.

RADIOLOGICAL PHYSICS

Physical Foundations of Radiology. By Otto Glasser, Ph.D., Edith H. Quimby, Sc.D., Lauriston S. Taylor, Ph.D., and J. L. Weatherwax, M.A. (Pp. 426; illustrated. 25s.) New York: Paul B. Hoeber, Inc.; London: Hamish Hamilton.

The four authors who have collaborated in the production of this textbook of radiological physics have kept in mind the needs not only of the young postgraduate preparing for a radiological diploma, but also of the more senior radiologist whose mind cannot so readily absorb modern physical concepts. In four chapters Glasser summarizes the history of radiology, the fundamentals of corpuscular and electromagnetic radiations, and the modes of interaction of radiation and matter. Weatherwax gives the essentials of electricity and magnetism, and their application in the different types of high-voltage generators and *x*-ray tubes; he also contributes an excellent chapter on the physical principles of *x*-ray diagnostic procedures. Taylor deals with the measurement of *x*-ray quantity and quality, and the chapter on protection will be of especial value to anyone installing a new apparatus or designing a new department. Quimby's contributions cover the whole field of radiotherapy and are full of suggestions which would improve the practice of even the senior radiotherapist; for example, the Table of Errors in Dosage on page 241 stresses the importance of measuring every physical factor as accurately as possible, for even so the dose given to a patient may be 20% out from what was intended. Her chapters on biological effects and on therapy records are particularly valuable, and there is also a full appendix of depth-dose tables.

The book is a model of lucidity and compression, and is free from misprints except for the transposition of the symbols D_0 and D_n on page 211; the references are well chosen and up to date, and the index complete; it should certainly be kept close at hand in every radiotherapeutic department.

A MEMOIR OF DAVID EDER

David Eder. Memoirs of a Modern Pioneer. Edited by J. B. Hobman. Foreword by Sigmund Freud. (Pp. 215. 8s. 6d.) London: Victor Gollancz. 1945.

This is a biography and appreciation of a remarkable man. A Jew born of parents in comfortable circumstances, David Eder found the study of medicine not altogether compatible at first, but once qualified he grew into an impassioned socialist, which was reflected in practical work in the East End of London, where he became one of the pioneers of the school medical system. This, however, was only after a period of medical officership in the revolution-ridden Republic of Colombia and far up the Amazon, where he got involved in the war between Brazil and Bolivia. Later he fell under the influence of Freud and Ernest Jones, then in Canada, and became one of the pioneers of psycho-analysis in this country.

Always concerned with the welfare of his race, Eder became closely involved in the Zionist movement at the end of the last war after the Balfour Declaration in 1917. He spent four arduous years in Palestine, and then came back to a busy psycho-analytic practice in London, where his broad humanity and wide knowledge of the world and its inhabitants stood him in good stead. For all his socialistic and Zionistic aspirations, however, he was not an optimist, as is shown by his final address as president of the Medical Section of the British Psychological Society, in which he attributes the hopes of progress so widely shared by the human race to a fantasy of victory over the universal aggressiveness with which we are born.

Appreciations of his activities as a socialist doctor are written by Harry Roberts; as a psycho-analyst by Edward Glover, who also analyses his character on psycho-analytic grounds; and as a Zionist by Leonard Stein and Sir Wyndham Deedes. Prof. Freud's appreciation of Eder's work is expressed in a foreword and several letters. This book is one which may be read in moments of relaxation with interest and a considerable amount of instruction.

Notes on Books

The 7th edition of Dr. PALUEL J. FLAGG'S *The Art of Anaesthesia* (J. B. Lippincott Company; 36s.) is a dogmatic, and therefore valuable, presentation of the subject, in a style redolent of the author's forceful personality. Brief descriptions are included of new anaesthetics and methods, but the author maintains with vigour that, because ether is the safest anaesthetic known, skill in its administration should be the first concern of every anaesthetist.

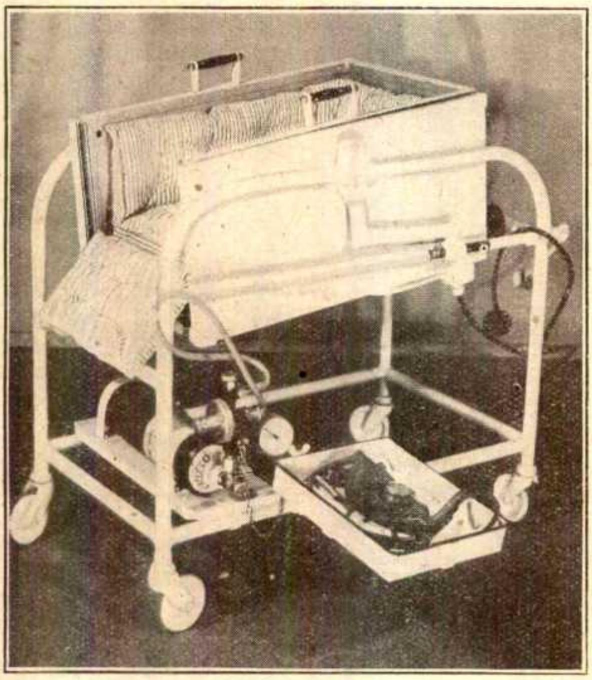
A new pamphlet entitled *Making Work Lighter*, the sixth of the series of Lighting Reconstruction Pamphlets, has been issued by the Illuminating Engineering Society, 32, Victoria Street, London, S.W.1. With comic illustrations in colour by Fougasse it differs in style from the preceding ones, and is intended primarily for distribution to all concerned with industrial lighting. The price is 6d. a copy.

Preparations and Appliances

A NEW ELECTRICALLY HEATED BABY'S COT

There has recently been put into service, at the Middlesex Hospital Maternity Department, an improved type of electrically heated cot. A feature of this cot is that the heating element is thermostatically controlled so that the temperature of the mattress and the bedding can be maintained at a uniform predetermined level, anywhere within the range of 60°–120° F.

The cot consists of two rectangular-shaped metal boxes placed one inside the other, both suitably flanged so as to form an adequate air space in which the heating element and thermostat are housed. The inside box is provided with ventilation holes in such positions as to ensure that a continuous current of warm air flows to the specially designed mattress, also box-shaped, which rests on a miniature bed spring. To prevent the mattress becoming scorched through contact with the metal, the cot is lined with heat-insulating material.



The "head" ends of both boxes are fitted with removable slides which permit of the baby being resuscitated by means of intubation, using the Gibberd and Blaikley apparatus, or having such treatment as may be necessary without its being lifted out of the cot or being otherwise subjected to a change of temperature.

The cot is attached to a trolley by means of two bearings, which incorporate the well-known Middlesex tilting device. The trolley is equipped with four ball-bearing castors, a rack for an oxygen cylinder, and a small tray for instruments. When not in use the tray, which is mounted on a pivoted stand, can be tucked away underneath the cot.

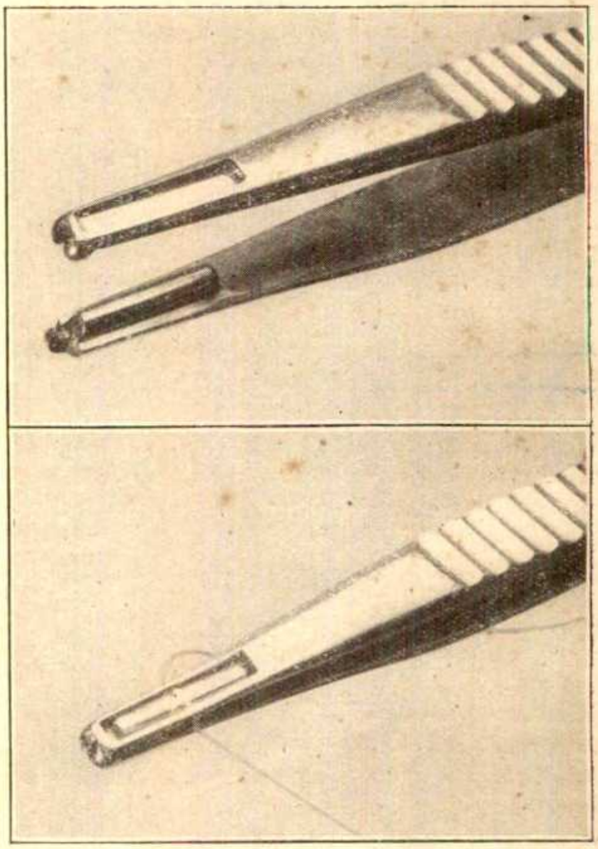
The apparatus, which was designed by Miss M. Williams, sister-in-charge of the maternity department, was constructed in the Middlesex Hospital workshops. The photograph shows the trolley with the cot "head" end removed.

NEW DISSECTING FORCEPS FOR "NO-TOUCH" TECHNIQUE

Major JOHN CHARNLEY, R.A.M.C., writes from the Orthopaedic Department, Shaftesbury Military Hospital:

Few dissecting forceps will grip suture material positively enough to make them suitable for tying knots in "no-touch" technique. The heavy finger pressure often needed soon tires the surgeon's fingers, and in some forceps the jaws may even open again and release the suture if excessive pressure be used.

The transverse serrations found behind the terminal teeth of an ordinary pair of toothed dissecting forceps are really of very little value in holding tissues; the efficiency of such an instrument depends on the design of the terminal teeth. When used in an attempt to tighten a knot the transverse striations lie parallel to the line of pull and thus allow the suture to slide and probably lacerates it, if it is soft catgut.



When the forceps illustrated are used as tissue forceps they work quite naturally on their terminal teeth; when used to tie a knot the suture is trapped in the fenestrum by the projection on the opposing blade. The suture material is therefore made to execute four right-angle bends within the grip of the jaws.

In practice the instrument holds wet catgut as delicately and powerfully as could be wished. It holds all other suture materials well, whether wet or dry, and is outstanding in performance with nylon. The best results are achieved when the habit has been learnt of deliberately seizing the suture some distance behind the point to ensure that it is well held in the trap. The soundness of the grip under the lightest finger pressure is impressive.

The present model is built on sturdy lines because it was essentially designed for bone work, but doubtless Messrs. Downs Bros., who have so easily surmounted the difficulties of the original design, could make others on a lighter scale.

Watson and Sons (Electro-Medical) Ltd., whose temporary head office is 76, Castle Street, Reading, have issued a leaflet on a new apparatus for the location of foreign bodies in the eye, which was developed in conjunction with Group Captain J. F. Bromley consultant in radiology to the R.A.F. A full description of th apparatus appeared in the *Transactions of the Ophthalmologica Society*, Vol. LXIII, "An Apparatus for Localizing Foreign Bodie in the Orbit," by J. F. Bromley and T. Keith Lyle.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MAY 19 1945

SYNTHETIC OESTROGENS AND CANCER

Not long after it had been announced that stilboestrol had some effect on the course of prostatic cancer, practitioners, acting on the assumption that cancer is a unity, give stilboestrol in other types of the disease, notably of the breast. Following desultory correspondence in the columns of this *Journal* the treatment of mammary carcinoma with stilboestrol was discussed at the Royal Society of Medicine,[1] and a committee was formed, with Prof. E. C. Dodds as chairman and Dr. Alexander Haddow as vice-chairman, to investigate the subject further. Not long afterwards we published two papers by Dr. Haddow and his colleagues on synthetic oestrogens and malignant disease.[2] These workers pointed out that many carcinogenic hydrocarbons also had the property of retarding the growth of both normal and malignant tissues. A few of these hydrocarbons had in addition slight oestrogenic activity. This interesting story is rounded off by the observation that oestrogens, both natural and synthetic, in certain circumstances are carcinogenic and in other circumstances have growth-retarding properties. In their first paper Haddow and his colleagues gave an account of the treatment by synthetic oestrogens of 40 cases of carcinoma of the breast and 33 cases of cancer elsewhere. The first of their cases was treated in February, 1941. In 10 of the 22 cases of mammary carcinoma given triphenylchlorethylene there was an initial regression of the tumour, which was unfortunately not maintained. In the most dramatic of these cases there was almost complete regression within three months of taking triphenylchlorethylene by mouth, but this was followed by a regrowth of the tumour and final death from cancer. Similar results were experienced in the treatment of breast cancer with stilboestrol. This painstaking work makes it clear that these remedies do not provide a cure for cancer; but another fact is added to the mass that has accumulated round this subject—namely, that synthetic oestrogens do have some retarding effect upon the cancer cell.

In their 10 cases of prostatic cancer treated between 1941 and 1943 Haddow and his colleagues observed symptomatic and general improvement in all except one, improved appetite and gain in weight, regression of the primary tumour in 4 cases and of secondary deposits in lymph nodes in 3; but in other cases, in spite of general improvement, the number and size of secondary deposits in bone continued to grow. As the stilboestrol treatment of carcinoma of the prostate was first introduced in 1940, we are not yet in a position to assess the results in terms of "cure." The progress of 7 cases of proved adenocarcinoma of the prostate treated with stilboestrol or stilboestrol dipropionate since March, 1940, has been described by Kahle, Schenken, and Burns.[3] A detailed account[4] [5] was given in 1942, and the present communication deals with the 5 of the original 7 patients who could be traced. One of the 5 died of urinary sepsis and heart failure. The findings are so important that the statements made by the authors are quoted: "In all 5 cases, including the fatal case, serial histologic examination showed definite regression in the carcinomatous tissues. There was a regression of metastatic osseous lesions, as demonstrated by serial roentgenologic examination, in the single case in which such lesions were present, and a regression of metastases to the lymph nodes in another instance." Massive doses of the drug produced no ill effect except in one instance of transient gynaecomastia. Another interesting point brought out is that in one case a recurrence of carcinoma occurred and the patient was equally responsive to a second course of treatment. The histological findings on sections taken at various periods throughout the treatment are also extremely interesting. The authors noted the following: "(1) In the untreated specimen the neoplastic cells present large vesicular nuclei, prominent nucleoli, and granular, reticular cytoplasm. (2) In the first stage of regression there is a decrease in the size of the nuclei associated with condensation of the nuclear chromatin. Nucleoli are no longer visible and mitoses are absent. Cytoplasmic vacuoles appear and are located predominantly at the bases of the cells. (3) In the second stage of regression the nuclei are pyknotic." These observations are highly important. The relief of symptoms—even though this may be only temporary—is an advance in therapeutics. The regression of the primary tumour is a very startling fact. But it is difficult yet to appreciate fully the significance of this work. If the effect of stilboestrol on prostatic adenocarcinoma cannot be repeated on adenocarcinomas in other parts of the body it is tempting to suggest that carcinoma of the prostate is different from other forms of malignant disease, which is tantamount to suggesting that cancer has more than one cause, just as an inflammatory reaction has more than one cause. Haddow and his colleagues did, however, observe an effect on carcinoma of the breast treated by stilboestrol and of the bladder treated by triphenylchlorethylene. We must emphasize that the benefit observed in these cases during treatment with synthetic oestrogens —and possibly, therefore, resulting from this treatment—was only transitory, and that the hopes raised in the sufferers and their relatives were finally dispelled by death. And although apparently dramatic results are obtained in the treatment of cancer of the prostate, the cautious reader will observe that bony metastases can grow and extend during a treatment which is associated with a regression of the primary tumour.

Kahle and his colleagues discourage speculation on the mode of action of stilboestrol. Theoretically the curative effect may result from action of the pituitary, or direct action on the cancer cells or on the testes and the cells producing the androgenic hormone. Another possibility is that the stilboestrol may upset the balance between androgens and oestrogens in the body and thus influence the growth of the new tissue. Others have suggested that the action may be due to some particular molecular configuration of the oestrogen. Dodds and his colleagues, responsible for the synthesis of the stilboestrol group of substances, have always pointed out that the structural resemblance of these substances to naturally occurring hormones is only superficial, and there would appear to be little advantage in speculating along these lines. Stilboestrol, hexoestrol, and dienoestrol are used in enormous quantities all over the world, mainly in the treatment of menopausal disturbances and the termination of lactation. The quite unforeseen use in the treatment of carcinoma of the prostate may prove to be the opening of a new and more hopeful chapter in the control of malignancy.

CHEMOTHERAPY OF TUBERCULOSIS

With the discovery first of arsphenamine, then of sulphonamides, and most recently of penicillin, effective drugs are now available for the cure of many of the infections of temperate climates. Others can be controlled by the prophylactic use of serum and vaccines. Among those conditions for which there is no effective cure are the common cold, influenza, and tuberculosis, and the last of these undoubtedly forms the biggest problem for chemotherapy. Numerous compounds have been tested for their action upon tubercle bacilli; most of the tests have been done *in vitro,* but some have been performed *in vivo,* mostly on guinea-pigs. Unfortunately the disease is so chronic, even in guinea-pigs, that a large number of animals are required over a long period to complete a single test; progress is accordingly slow. Among compounds which have been demonstrated during recent years to inhibit the growth of tubercle bacilli *in vitro* may be mentioned 2 : 4-dichlorobenzophenone[1] (active 1 : 100,000); sulphur compounds, especially mercaptobenzothiazole[2]; 3 : 5-diodo-2-hydroxylbenzoic acid[3] (active, 1 : 10,000); and 3 : 6-diamino-10-methylacridinium iodide[4] (active *in vitro* 1 : 250,000, but inactive *in vivo*). The compounds shown to be active *in vivo* have been mostly salts of heavy metals. Of these, gold compounds have received the most attention and are the best known. During the past twenty years preparations such as sanocrysin or solganal B have been used extensively in the treatment of human disease. Experts on tuberculosis are still far from unanimous about their value. Cadmium sulphate has been recommended as being as good as sanocrysin, while being cheaper and non-toxic.[5] In Germany a preparation of copper called "ebesal" was found to be useless for human pulmonary tuberculosis.[6] In a review in 1940 Findlay[7] concluded that none of the remedies up to that date had been shown to have a decisive influence on the course of the human infection.

In 1941 a more hopeful chapter was opened by the work of Hinshaw and Feldman[8] on sulphone derivatives. The earlier sulphonamide compounds had proved disappointing when applied to tuberculous infections, but these workers demonstrated that promin (sodium *p,p′*-diamino - diphenyl - sulphone - N,N′ - didextrose sulphonate) arrests but does not completely suppress tuberculous infection in guinea-pigs. However, when promin (or promanide, as it is known in this country) was tested in human tuberculosis the results were disappointing. It caused toxic effects such as anaemia, cyanosis, agranulocytosis, gastro-intestinal disturbances, and other symptoms, and its therapeutic action was not very pronounced.[9] It was clear that promin was not the long-awaited remedy, though perhaps it might point the way towards it. The most successful method of using promin was that reported in 1942 by Tytler and Lapp,[10] who applied it locally to tuberculous ulcerations; but this report does not seem to have been amplified or confirmed. Various improved forms of promin have been announced, the most hopeful being promizole (4′-2′-diamino-phenyl-5′-thiazole sulphone),[11] which is somewhat similar to sulphathiazole; but clinical reports are not yet available. The sulphone group of compounds is the most promising one discovered so far. A most interesting development, however, has recently been reported[12]—namely, the use of the antibiotic substance, streptomycin, against tuberculosis; this is described in more detail on another page. In guinea-pigs it is as effective as promin.

The latest example of bactericidal action against tubercle bacilli *in vitro* is reported by Faulkner,[13] who has shown that diethylstilboestrol (4 : 4′dihydroxy-α : β-diethyl stilbene) is active in this respect. In a previous paper she had demonstrated that stilboestrol is bactericidal *in vitro* for Gram-positive organisms such as staphylococci, haemolytic streptococci, and diphtheria bacilli. When incubated at 37° C. for 24 hours in an aqueous medium, tubercle bacilli are killed by stilboestrol at a concentration of 1 : 20,000. If the bacilli are suspended in a medium containing 25% of serum the activity of the compound is much reduced, and a concentration of 1 : 3,000 is needed. In the light of these results it is interesting to recall clinical experience on the association of tuberculosis and pregnancy. During pregnancy phthisical women may appear to improve in health, but in the puerperium the tuberculous disease usually advances more rapidly. Tuberculosis of the placenta is very rare, but it occurs occasionally in women with acute generalized tuberculosis or advanced chronic pulmonary tuberculosis. It is stated in Faulkner's paper that the antituberculous action of stilboestrol is being investigated *in vivo,* and the results will be awaited with interest. But in view of the low activity in the presence of serum, and the long history of previous disappointments in this field, it seems most probable that the search for an effective remedy for tuberculosis will still have to go on. The chemotherapy of tuberculosis should be investigated on a much greater scale than in the past, once the war is over.

DIMETHYL PHTHALATE AS AN INSECT REPELLENT

The fight against insect-borne diseases has in this war been an important part of the fight against the German and the Jap. It has been conducted with the weapons of immunization and drugs, by new methods of killing the insects, and by protective clothing and repellents. A repellent which would prevent insects from biting ought to be an ideal protection; but unfortunately a bloodthirsty insect is not easily put off. Citronella, the material chiefly used before the war, was effective only for quite a short time, though its pungent (and eventually repugnant) odour seemed very persistent to the human nose. Systematic research revealed several new repellents that are more efficient and more pleasant. One of the most widely used is dimethyl phthalate. It is a colourless and practically odourless oily liquid, boiling at about 280° C. and less than 1% soluble in water. Together with other phthalic acid esters it is widely used in industry as a plasticizer, but, according to Lehmann and Flury, no cases of industrial poisoning are known. A point which should be remembered in handling or using the substance is that it softens and dissolves plastics, some of which are in common use; therefore it should not be allowed to contaminate certain buttons, plastic jewellery, or fountain pens, and possibly some kinds of artificial silk may be attacked.

Dimethyl phthalate can be applied to the skin without harm, though it may cause smarting on a few sensitive areas (such as eyelids, lips, or scrotum), which should be avoided. This treatment is easily carried out by anyone and will prevent the bites of mosquitoes for three to five hours. When 50 to 100 c.cm. was sprayed on to a suit of clothing, protection from *Aëdes taeniorhynchus* was obtained for about a week. Similar results were obtained with *Aëdes aegypti* and *Anopheles quadrimaculatus* in laboratory tests. Since mosquitoes readily bite through clothing, this method is a valuable adjunct to skin application.[1] Dimethyl phthalate has been successfully used in the field as a repellent for *Phlebotomus papatasi*, the vector of sandfly fever. No satisfactory method of controlling the disease or controlling the vector has yet been devised. The usual procedures, such as screening, are ineffective because of the small size of the fly. In an experiment carried out in the Eastern Mediterranean area[2] the daily use of dimethyl phthalate by troops reduced the complaints of bites and the incidence of the disease. For protection against fleas dimethyl phthalate also shows promise. Laboratory tests[3] of forty-six possible repellents were made by exposing a treated human arm to a large number (500–1,000) of dog and cat fleas (*Ctenocephalides spp.*). Dimethyl phthalate was high on the list of efficiency and was devoid of certain objections, such as toxicity to man and high cost. Clothing treated with it will give protection from flea attacks for several days. As well as repelling biting insects, dimethyl phthalate will prevent the attacks of the mites *Acariscus* and *Eutrombicula*. The larvae of these mites are called "chiggers" in the U.S.A., and their attacks are similar to those of the harvest mite, to which they are related. The repellent is applied to all the openings of the clothing and is said to give good protection for thirty days after treatment.[4]

Dimethyl phthalate is not the only new promising repellent. Indalone (*n*-butyl mesityl oxide oxalate) and "Rutgers 612" (2-ethylhexanediol-1;3) have been widely employed,[1] while the insecticide pyrethrum also acts as a repellent by its paralytic effect.[3] Some species of insect are most sensitive to one and some to another. For example, "Rutgers 612" has proved most effective against *Aëdes*, whereas dimethyl phthalate is most effective against *Anopheles quadrimaculatus*. Indalone is of little value for the latter but is highly efficient for the stable fly, *Stomoxys calcitrans*. To obtain the very best possible results it may be desirable to choose the most suitable repellent for the circumstances or possibly to make a universal mixture.

PLANNING IN PAEDIATRICS

Both in the report of the Goodenough Committee and in the report of the Royal College of Physicians on medical education it was stressed that more attention should be paid to paediatrics. The R.C.P. Planning Committee recommended "that paediatrics should be regarded as a major clinical subject," and now a Paediatric Committee of the College—widely representative not only of paediatrics but also of general medicine, public health, psychiatry, and obstetrics—has endorsed this, and in an interim report sets out detailed proposals for undergraduate and postgraduate education in this subject. It is stressed that throughout pre-clinical training more attention should be paid to normal growth and development of children and to morbid processes which are peculiar to childhood. In the clinical stage it is recommended that a period of not less than one-third of that devoted to clinical medicine should be set aside for clinical paediatrics. This is to be supplemented by work in a neonatal department while the student is taking his course in obstetrics; by visits to a child welfare centre; and by opportunity for observing chronic diseases at special "homes" and convalescent homes. For a medical school with an annual entry of 80 to 100 students a paediatric department of 100 beds is suggested, with additional beds for tonsillectomy cases and for infectious diseases. The general supervision of all children admitted should be undertaken by the paediatrician in association with the surgeon and specialist who may be concerned with treatment. For the staffing of such a department, which it is hoped will have university status, a whole-time director of professorial rank is recommended. The remaining staff is on the following lines: one whole-time assistant, preferably with the rank of reader in the subject; one whole-time senior assistant; one registrar; two part-time paediatricians—on the hospital staff; and resident officers. It is also suggested that from the departments of psychiatry, radiology, and pathology a member of the staff should interest himself especially in the problems of childhood. Surgeons and specialists would also be appointed to the department, and stress is laid upon the great importance of the nursing staff being on the Sick Children's Nurses' Register.

These considerations of curriculum and staffing lead on to the place of paediatrics in the final examination, with special reference to the Conjoint. Questions on paediatrics in the medicine paper and a separate clinical examination are recommended, with paediatric examiners taking part. Postgraduate training is discussed for four groups: consultant paediatricians to be trained on the lines already agreed upon for consultants in general by the three Royal Colleges; consulting physician-paediatricians with a modified training as an interim measure until more of the first group are available; general practitioners requiring refresher courses; and medical officers in the child health service, who should, it is recommended, be closely linked to the hospitals so as to ensure working association between preventive and curative work. It is apparent in this report that the experience of Canada and the U.S.A. has been carefully studied: the recommendations follow closely the established practice across the Atlantic, so that the claims of paediatricians, great as they may appear in the eyes of those accustomed to what the Goodenough Committee described as "inadequate" in this country, are not in the nature of fancy experiments but an attempt to keep pace with the developments of a subject "vital to the future of the nation."

STREPTOMYCIN, A NEW ANTIBIOTIC

The brilliant success of penicillin has led to vigorous search for other antibacterial products derived from mould and similar micro-organisms. Many such substances have now been described—e.g., gramicidin, clavacin, helvolic acid, etc.—but none of these has come into extensive clinical use. Recently two promising compounds named streptothricin and streptomycin have been isolated by Waksman and others[1] [2] from certain species of soil actinomycetes. They resemble each other in many respects, but streptomycin is likely to prove the more valuable of the two. It is obtained from *Actinomyces griseus* grown under certain conditions. Like streptothricin, it is highly stable and resists moderate heat, storage, and the action of most other organisms; thus it is in marked contrast to penicillin. Chemically it appears to be an organic base. It is soluble in water but not in ether or chloroform. It inhibits the growth *in vitro* of *B. subtilis,* the tubercle bacillus (human strains), *Bact. coli, Staph. aureus, Brucella abortus, Bact. aerogenes,* and various other Gram-negative organisms of the *Salmonella* or dysentery groups. It has a moderate inhibiting effect upon the growth of *Proteus, Sal. aertrycke,* and *Ps. pyocyanea.* It has no action upon moulds or *Trypanosoma equiperdum.* Its toxicity for animals is fairly low, the lethal dose for mice of a purified preparation being 7 g. per kg. In most of these respects streptothricin is similar, but its antibacterial action is less powerful and is restricted to a smaller number of organisms.

The chief promise of these compounds lies in their action on the Gram-negative bacilli, many of which are resistant to both sulphonamides and penicillin; the results of clinical trials will be awaited with interest. So far none have been reported (perhaps because only small quantities of the compound are available), but animal tests have been carried out in mice. Streptomycin has been very effective in protecting mice against a mixed infection of *Proteus vulgaris* and an anaerobic streptococcus, both obtained from a case of severe human infection. Favourable results have followed treatment by streptothricin of mice and chick embryos infected with *Sal. aertrycke, Sal. schottmülleri,* or *Br. abortus,* or when similar infections due to *Sal. schottmülleri, Ps. pyocyanea, Shigella gallinarum,* or *Br. abortus* were treated with streptomycin. In the United States there is trouble due to a disease called tularaemia, which is unaffected by sulphonamides and penicillin. In a recent year 1,600 cases occurred, with a mortality of 3 to 5%. Heilman[3] has now reported that the causative organism, *Pasteurella tularensis,* is more than thrice as sensitive to streptomycin as *Bact. coli,* and that infections in mice can be completely prevented by this compound. The most interesting of all applications of streptomycin, however, is its possible use against tuberculosis. As observed above, it inhibits the growth of tubercle bacilli *in vitro.* Recently Feldman and Hinshaw[4] have described a trial on tuberculosis in guinea-pigs, similar to their previous trials with promin. Guinea-pigs were inoculated with virulent bacilli and treated with doses of up to 6,000 units daily for sixty days. At the end of this time there was widespread tuberculosis in untreated control animals, while in the treated animals it was hardly detectable microscopically; viable bacilli, however, were usually still present. These results are interpreted as showing that the antituberculous activity of streptomycin is comparable with that of promin and similar compounds. Further work will be awaited expectantly. When streptomycin and streptothricin become more widely available in large enough quantities their clinical applications will deserve careful study.

SEX HORMONES FOR MELANCHOLIA

With increasing age high spirits tend to fall. This is as true for the mentally disordered as for the sane, and as age creeps on mania becomes rarer and melancholia commoner. In the involutional period of life a depressive colouring to mental illness is the rule rather than the exception, and illnesses of many different kinds may then show depression as their most prominent symptom and be difficult to disentangle. Patients who on first admission to hospital are diagnosed as suffering from involutional melancholia may turn out to be suffering from an organic disease such as cerebral arteriosclerosis, others from a late schizophrenia, and others from a recurrent manic-depressive syndrome. Still another type of melancholia has been found to arise in people of a rigid, unbending, conscientious, and puritanical temperament—the so-called obsessional personality. In them there are fair hopes of spontaneous recovery—hopes which have been turned into high probabilities by the advent of convulsive therapy.

Danziger and his co-workers[1] [2] have pointed out what may prove to be yet another small but distinct group, consisting of patients who became depressed with a failure of the endocrine activity of the sex glands. The evidence in favour of the existence of this group is so far purely clinical. The possibility of endocrine failure in women as the cause of the depression is suggested by a close temporal relationship between its onset and the menopause. If patients are chosen in whom this relationship holds and the illness is a first attack, Danziger shows that benefit follows the administration of oestrogen, and the bigger the dose the better the result. From cases reported in the literature 1 of 3 recovered or was greatly improved with doses of less than 3,000 international units a month, 9 of 13 with doses of 24,000–45,000, and 22 of 23 with doses of 80,000–600,000. In men there is no such simple indicator of endocrine change as the menopause. But it seems that even in a mixed group of patients the response to androgens is better than could have been expected from the natural history of the disease. Even if this method of treatment does not prove in general to have better prospects than convulsive therapy it clearly needs further study. A minority of patients, in whom there is no reason to suspect either a late schizophrenia or an organic dementia, still fail to get better after treatment with fits, or, having once improved, again relapse. It is possible that among them are those whose illness is due to endocrine change. Furthermore, the pathogenesis of these illnesses is so little understood that more information about a possible physiological basis would have theoretical as well as practical importance.

The next session of the General Medical Council will begin on Tuesday, May 29, at 2 p.m., when the President, Sir Herbert Lightfoot Eason, will take the chair and deliver an address.

THE CHILD'S ACQUISITION OF SPEECH

BY

MARY D. SHERIDAN, M.D., L.R.A.M.

Assistant School Medical Officer, Manchester

In the course of a research into defects of articulation in school-children I discovered, with some astonishment, that although the child psychologists have already built up a considerable literature regarding the development of *language* in the young child, there were apparently no records of any large-scale observations concerning the normal acquisition of the actual speech sounds. Most of this work on the acquisition of language has been done by non-medical psychologists recording the linguistic development of one child or of a small group of children, usually the offspring of highly intellectual parents. The latest English observers (to mention only a few) include M. M. Lewis, Susan Isaacs, C. W. Valentine, and G. Seth (writing in collaboration with D. Guthrie, the laryngologist); while the whole field of mental development in relation to language development has recently been admirably surveyed by A. F. Watts. Leopold Stein, who now works in London, approaches the subject from the point of view of the medical psychologist who is also a philologist and a speech therapist, and for this reason his work is particularly valuable.

The reason for this apparent neglect of research into the acquisition of normal speech sounds was immediately obvious when I began my own investigations. The difficulties are four-fold. (1) The young child, in passing from the stage of babbling to the stage of fully articulate speech, makes use of a number of sounds for which there is no recognized phonetic symbol, so that accurate charting is sometimes impossible, and the recorder is obliged to use those symbols which most nearly represent the child's speech. It is therefore essential that the recorder should be an experienced phonetician. (2) It is unscientific to draw conclusions from incomplete records of a child's speech, but it is exceedingly difficult, in the time at one's disposal, to persuade some children to demonstrate the full range of their phonetic usage. The observer must therefore be skilled in the examination of young children. (3) It is unwise to generalize from the speech of one child or of a small group of children. It is therefore necessary that the recorder should have facilities for observing large numbers of young children with widely differing intellectual, social, and geographical backgrounds. (4) In order that speech sounds may be normally acquired it is necessary that the child's mechanism for speech and hearing should be perfect. It is therefore desirable that the observer should be a medical officer experienced in detecting even slight deviations from the normal anatomical, physiological, and psychological standards.

In the course of some 3½ years I have been able to collect complete records of the speech of 650 children under the age of 5 years. Of these, 620 were children attending nursery schools and clinics, while the remaining 30 were mostly children of friends and relations whom I was privileged to observe over prolonged periods. In addition to these there were dozens of other children encountered in nurseries, trains, shops, even in bus queues, who provided me with fragmentary samples of their speech. The records were charted according to age (in 1/4-year periods) and sex.

The Child's First Efforts

From the detailed analysis of this mass of material a definite pattern gradually emerged. Following the infant's realization that the speech and gestures of his adult attendants possess meaning—a realization which normally occurs about the age of 8 to 9 months—he begins to make responsive sounds whenever he is spoken to, and to play with his own vocal sounds when he is alone. These sounds are usually of the repetitive variety—"bab-bab-bab," "mum-mum-mum," "dad-dad-dad"—sounds which are promptly appropriated by the parents as proper names. Soon this game is carried a step further by the child's recognition and subsequent echoing of the cadences of adult speech, so that his babbling assumes normal vocal inflections or "tunes." Listening outside the nursery door to this tuneful babbling, it is often impossible to believe that the child is not using articulate speech. He uses most of the vowels and consonants, but the sequence of utterance is so undisciplined that the result is unintelligible. At this stage the child's comprehension of speech, which rapidly outstrips his performance, is often remarkably good. ("Shut the door, please," "Look, here's Daddy coming," and "Never mind, I'll kiss it better," says the mother, and he immediately responds.) The child now realizes that speech is the most convenient form of communication. The use of real words follows. Often this real word is comprehensible only to the mother. It is imperfectly articulated and therefore difficult to interpret, but since he uses it consistently for any given object or activity his mother rapidly learns to understand him. Just as the experienced ear makes up the missing frequencies from a telephone conversation, although only about 70% of the speech sounds are actually transmitted, so that the listener is unconscious of any deficiency, so the mother listening with the ear of knowledge and love will assure one that the child's speech is "perfectly plain," and that "he can say anything," although the recorder is struggling to interpret a glorious jumble of phonetic substitutions, elisions, and omissions.

For some time not only the tunes of speech but the loudness and shrillness of the voice itself are greatly exaggerated. I have observed this many times in children of every social grade and level of intelligence. They tend to shout, using a very wide range of notes, as if a nice discrimination of pitch and intensity comes only with more experienced listening and imitation. The first "words" or sound groups often consist only of vowels and a tune, and are frequently accompanied by an explanatory gesture; thus the child says "i—i" ("dicky") and points at the sparrow in the garden, or, handing the last brick, "a—aw!" ("that's all!"). Or the word consists of a labial consonant, a vowel, and a tune; thus "baw" = "ball," "mow" = "mouth," "woh a?" = "what's that?".

Vowels

The vowel sounds used re-echo the accent of the environment in which the child lives, but certain deviations from the environmental normal are constantly observed. The long vowels—"oo" (pool), "aw" (paw), "ah" (palm), "er" (pearl), "ee" (peel); and the short vowels—"u" (as in hut and in put), "o" (hot), "a" (hat), "e" (set), "i" (sit), appear some time before the diphthongs; but frequently the sound "e" (set), and less frequently the sounds "u" (hut and put), and rarely "o" (hot) and "i" (sit), are lowered to the sound "a" (hat); while "u" (put) is lowered to "o" (hot) so that "egg" = "agg," "head" = "had," "pull" = "poll"; and less frequently "foot" = "fat," "duck" = "dak," "cot" = "cat," even "bib" = "bab," although more usually the "i" (bib) becomes "e" (beb). The diphthongs are difficult to write in ordinary script, but they are the vowel sounds in the words "mail," "mile," "boy," "sole," and "cow." They consist of two vowel sounds closely joined together, the first of which (in English usage) is generally given more weight and resonance than the second, to which the tongue glides only lightly and briefly. The diphthongs appear to cause the child considerable confusion at first, so that the latter less prominent half is often omitted; thus "lady" = "leddy," "now" = "nah," "noise" = "nawse," although occasionally the latter half is used—thus "lady" = "leedy," "cow" = "coo." Later when the presence of two sounds has been appreciated the diphthongs themselves are sometimes interchanged; thus "coal" = "cowl," "day" = "die," and less frequently "my" = "may." I have recorded these apparent Cockneyisms over and over again in the speech of children who have never heard a true Cockney vowel in their lives.

Consonants

While the vowels are being acquired consonants are rapidly tacking themselves on to them—first at the beginning of the word (since the initial consonant is normally spoken with more weight than the terminal one and therefore is more rapidly appreciated by the child's inexperienced ear) and, much later, at the end and in the middle of the word. The first consonants to be acquired are usually the nasal sounds (m and n) and the labials (b and p), followed by the "front stops" (t and d). Less often the "back stops" (k and g) are used first, but whichever pair the child first acquires he normally uses only that pair for both front and back stops for an appreciable time; thus when the front stops are chosen, "top" = "top" and "doll" = "doll," but "doggie" = "doddy," "cup" = "tup," "cat" = "tat"; or where the back stops are used, "cup" = "cup," but "two" = "koo," "dirty doggy" = "gerky goggy," "toy tank" = "koy kank."

The sounds represented in ordinary script by the letters "r," "l," "w," and "y" are usually late in appearing, and are frequently interchanged, so that a "rabbit" may be a "wabbit" or a "labbit" or a "yabbit"; a "lion" may be a "rion" or a "yion," and so on; but whichever sound the child chooses the substitution is usually consistent for a period of some weeks or months. The last single consonant sounds to be acquired and finally differentiated are "h" (which is a mere breathed sound) and those forming the group represented in ordinary script by the letters "z," "zh" (as in "pleasure"), "v" and "th" (voiced, as in "mother"), and their unvoiced equivalents "s," "sh," "f," and "th" (as in "thing"). These sounds appear to give the child considerable difficulty, and even when they have been acquired they are often interchanged; thus "father" = "farver," "another" = "anozzer," "thing" = "fing," "finger" = "thinger," "five" = "thithe" (sometimes "five" = "pibe," another auditory confusion), "sweeties" = "feetie," "sixpence" = "thikthpenth." Of all the sounds the unvoiced "th" ("thing") is the last to be fully appreciated. It is so rare before 5 years of age that of my 650 cases only 20% of the girls and 9.7% of the boys used it correctly. There could hardly be a prettier demonstration of the auditory basis of speech than this, since we know from Harvey Fletcher's investigations that the phonetic force of the voiceless "th" is the least of all the speech sounds, being 680 times less than that of the vowel sound "aw" (paw).

While the child is still in the process of differentiating these last two sound groups (the "r, l, w, and y" group and the "s, f, th" group) the first attempts at double consonants are being made. At first all double consonants are reduced to one single sound; thus "train" = "tain," "cream" = "keam," "please" = "pease," "pretty" = "pitty," "bridge" = "bid," "spoon" = "poon," "star" = "tar," "school" = "kool," "jam" = "dam" (the letter "j" is really two sounds—d–zh); "chip-chop" = "tip-top" (ch is really t–sh). In other words, the child once more at first chooses the sound which is easiest to hear and uses it alone; but as he becomes aware of the presence of a double sound an interesting fact emerges. He will usually make use of his habitual single substitutions in these double sounds, so that "three" = "fwee" or "fyee," or even "flee," "tree" = "klee," "drink" = "dyink," and "scream" becomes the wonderful tongue-twister "thkleam."

Speech Development

It has been pointed out that the initial consonant sounds appear before the central and terminal ones. This observation applies to all sounds which are difficult to hear and includes even weakly stressed syllables and vowels. For instance, the neutral sound which ends so many of our spoken English words (china, motor, paper) is often not appreciated for a considerable time. But the child is so conscious of the cadences and rhythm of speech that he will invariably leave a space for the unspoken sound, which might be compared to the rest in music or, perhaps more accurately, to the metrical pause in prosody, since there is seldom an actual break, but rather a lingering over the preceding vowel. Thus I have many times recorded this gradual evolution of the words "pussy cat":

pu: pu
pu: pu ta ("a" as in "hat")
pu: i ta
pu: i tat
pu: i cat
pussy cat

These patterns of speech development are so constant, the cases of anatomical defect are so rare (with the exception of malocclusion of the jaws, which I have noted elsewhere as being closely associated with defects of "s" in slightly older children), and the child's tongue finds it so easy to perform athletic feats impossible to the adult, whose phonetic habits are firmly established, that I cannot believe these substitutions are due to any muscular incoordination. I feel sure they must be true auditory confusions. The fact that nouns and verbs are the first grammatical entities to be acquired also points to the auditory basis of speech, since not only are they focused upon the child's attention because they are associated with his bodily activities, but they also receive greater phonetic emphasis than any other parts of speech. Harvey Fletcher has shown that good hearing over the upper frequencies of the speech range (i.e., 4,096 to 8,192 cycles per second) is necessary for the accurate appreciation of the sounds "s," "f," and "th" in nonsense syllables. My own observations on the speech of various groups of school-children indicated that both the child with impaired hearing and the mentally retarded child had difficulty in distinguishing these sounds—the first because he is *physically* incapable of appreciating their upper components, the second because he is *functionally* unable to recognize fine distinctions, although his actual hearing for pure-tones may be normal. Just as his muscular control is clumsy and his mental processes immature and slow, so are his speech patterns infantile in character.

This interesting question therefore arises: Are these consistent patterns of speech occurring in the normal course of development the result of some structural immaturity (analogous to the hypermetropic eye of childhood) in the auditory nerve itself or its association areas; or are they the result of a psychological immaturity—in other words, of that faculty of attention and discrimination which is listening? I incline to the latter view, since I have observed many times how rapidly these infantile habits of speech improve when the child is introduced to the salutary influences of community life in a nursery school. In my experience baby speech most commonly persists in the neglected child, in the spoilt only child, and in the adored youngest of large families. The only child of intelligent parents usually acquires perfect speech very early; but the over-indulged child, to whom everything is given if he merely points and whose parents consider his defective language to be unique and charming, and the neglected child, to whom nobody troubles to talk, these have no incentive to improve their articulation. I have observed the same "environmental" retardation occurring, even more dramatically, in the case of twins. In their small world nobody else matters but one's twin and one's mother, and between them they establish a rudimentary vocabulary which is sufficient for their entire nursery existence, and which is often so completely unintelligible to the rest of mankind that it has been thought that they have evolved a new language. On phonetic analysis, however, I have always found that the words used are recognizable but degenerate forms of normal infantile speech. The best remedy for all these children—neglected, isolated, or over-indulged—is daily attendance at a nursery school. It should be remembered that this intellectual neglect may occur in hospitals and in residential nurseries although the child's physical needs receive devoted attention. Nurses in charge of young children should never be allowed to forget their responsibilities towards the child's mental growth.

Speech Therapy

The question of formal speech therapy in the absence of gross anatomical defect, such as cleft palate, does not usually arise before 5 years. The child who by 2½ years has not made any attempt to develop normal speech, however slowly, along the lines indicated above should be suspected of deafness or mental retardation and the appropriate expert consulted. But there can be no more question of teaching the child to speak before he has made his own spontaneous efforts than there can be of teaching him to walk before he has made an attempt to stand and to crawl. The child should be presented with good models and should be encouraged to speak in every possible way by being played with, spoken to, and, just as importantly, listened to. For this reason the play methods of the day nursery school, where the child is provided with toys, creative material, new experiences, and intelligent guidance, are usually of the utmost benefit to his linguistic and therefore his general intellectual development. When infantile habits of speech persist after 6 or 7 years old the assistance of an experienced speech therapist becomes essential, or the child will stabilize his defects so that they become increasingly difficult to correct. Moreover, his scholastic progress, especially in the linguistic subjects, will be seriously delayed. The child who does not readily respond to this expert teaching should be examined by the school medical officer with a view to determining whether his intelligence quotient and his hearing for pure-tones are normal.

Summary

The speech of 650 children under 5 years old was examined and phonetically recorded. A consistent pattern of speech development was observed. The auditory implications of this speech pattern are discussed.

THE SAN JUAN EARTHQUAKE

A MEDICAL NARRATIVE

Early last year the British press contained brief references to an earthquake that had occurred in San Juan, Argentina. The scantiness of the information available at a time when most space in the general press is necessarily reserved for war news lends particular interest to an account[1] of this disaster by Dr. Carlos I. Rivas of the Instituto de Clínica Quirúrgica of Buenos Aires. At first glance one is struck by the familiarity of the scenes depicted in the accompanying photographs. A whole street lies in ruins, with nothing standing but a few sections of wall. Another picture shows the crushed remains of a car buried under a pile of masonry. In a third, two rescue workers stand by an excavated corpse.

San Juan is a town with a population of 20,000, the capital of the province of the same name. It is west and slightly north of Buenos Aires, and about 700 miles away. On the evening of Jan. 15 a brief report was received in Buenos Aires that there had been an earthquake at San Juan; few details were available. On the following morning it was heard that the incident was serious, and that many injured were in urgent need of attention. An emergency scheme was quickly improvised, and on the next day a train left Buenos Aires carrying 20 doctors, 30 nurses, and abundant surgical equipment. At the same time a team of 20 surgical specialists, including Dr. Carlos I. Rivas, assembled at the El Palomar airfield, where they were joined by General Perlinger, Minister of the Interior, and took off for Mendoza in two military aircraft. On arrival at Mendoza, about 100 miles from their ultimate destination, they learnt that "the extent of the tragedy is not yet known, but each fresh news seems more unfavourable."

The rest of the journey was made by road, and as they approached the outskirts of the city they were greeted by a sight which the cinema had made familiar, but which they had hardly expected to see for themselves—an exodus of survivors in columns which grew more dense as the city limits were approached. Further on they were confronted by an incredible spectacle. "The San Juan earthquake involved the complete destruction of the city." As the car lurched through streets covered with debris, exclamations of amazement escaped from the lips of the surgeons, but soon they were silent—"all their energies concentrated in their eyes." Freak effects were to be seen—a dining-room exposed, with a meal uneaten and undisturbed on the table. At last they reached the Hospital Rawson, which was found to have been partly destroyed. Patients had been transferred to the hospital garden, where they lay in bed surrounded by relations and friends. The medical staff had been continuously engaged in administering first aid to an ever-growing stream of injured survivors. A little further, on a smooth lawn, lay hundreds of corpses in rows, many of them in grotesque attitudes, while survivors seeking missing relatives or friends moved among them in an anguish of fearful expectation.

It was clearly impossible to establish a suitable medical organization in such surroundings, and the party therefore chose a building in a reasonable state of preservation—the Colegio Nacional—and, with the aid of six soldiers, worked desperately to transform it into an emergency hospital. From a photograph reproduced by Dr. Rivas this seems to have been done very efficiently. This preliminary task was completed by 8 p.m., and by midnight, when the additional medical personnel arrived by train, a hundred patients had been treated. With the arrival of these reinforcements, available personnel was organized into five surgical units, who set to work on a constantly renewed emergency hospital population of 120 patients. The principle adopted was to give whatever attention was needed to render each patient fit for transportation as quickly as possible to a suitably equipped surgical centre elsewhere. As would be anticipated, there was a predominance of fractures of the lower limbs and of chest injuries. Lesions of the vertebral column were fewer.

After several days of uninterrupted work, some hundreds of cases had been dealt with and the work of the Buenos Aires mission was completed. Although the thousands of dead, and the hundreds of wounded evacuated to Mendoza and now enjoying rest, food, and medical attention represented a solution of the medical problem, Dr. Rivas says that the members of the mission were acutely aware that a far greater social problem remained. As the surgeons gazed at a convoy of men, women, and children leaving their desolated town to start a new life in some unfamiliar place, they did not know whether to be moved more by compassion for their misfortune or by admiration for their stoicism.

This account by Dr. Rivas is not intended to be anything but a personal narrative. It gives no details of treatment or of the lesions encountered, and does not refer to the auxiliary services—emergency food and water supplies, clothing, and rest centres—that a totally devastated town might be supposed to require. There is only a passing reference to an event which further clouded an experience already full enough of misfortune—an accident to one of the planes which cost the lives of some of Dr. Rivas's surgical colleagues. Nevertheless the reader is left with the impression that the surgeons who were called upon so dramatically to help in this unpredictable disaster brought to their task a high degree of fortitude and resource.

MEDICAL EDUCATION IN THE U.S.A. BEFORE THE CIVIL WAR

Medical Education in the United States Before the Civil War, by Dr. William Frederick Norwood, with a foreword by Prof. Henry E. Sigerist, is published in Philadelphia by the University of Pennsylvania Press, and in London by the Oxford University Press (price 36s.). This volume of just over 480 pages with its extensive bibliography is an important contribution not only to the story of American medicine but also to the cultural history of the United States. It surveys the rise and progress of the American system of medical instruction and the institution of medical learning up to the time of the Civil War—a period of gradual progress in raising the standards of professional education, for it saw a renaissance begun at Harvard in 1771 and emphasized many years later at Johns Hopkins.

The author in his review of all the colleges throughout the U.S.A. has been thorough. We cannot find any that have been omitted. During the first two centuries of colonial history, instruction by apprenticeship was the prevailing system. Ere long European influence began to bear fruit. London, Paris, and especially Edinburgh, were attractive to young Americans after 1750, who on their return became preceptors and lecturers. In the first medical schools there was generally a provision for the M.B. degree as well as a doctorate, but as so few of the baccalaureate candidates ever returned to qualify for the advanced degree it was abolished in the second decade of the nineteenth century in favour of the M.D. After several years of struggle Elizabeth Blackwall in 1847 gained admission to Geneva College and graduated two years later. In 1850 forty women entered the Pennsylvania Women's Medical College, from which Dr. Ann Preston accepted the chair of physiology and hygiene and thus became the first woman medical professor. By 1865 four medical colleges for women had been established. The most significant event of this period was the founding in 1847 of the American Medical Association. It was conceived as an instrument of reform and charted a course for the elevation of medical education; it rescued the early American profession from being largely empiric.

Dr. Norwood has paid much attention to documentation while maintaining the interest of his story. His book will be found valuable in exploring the subject of the medical birth of a nation.

The old Foundling Hospital, established in 1740 by the philanthropist Capt. Thomas Coram, has had many medical friends. Some years ago the boys and girls and those in charge of them moved from the large site in Bloomsbury to new quarters at Berkhamsted in Hertfordshire. It is a sign of the times that the Foundling Hospital Schools are in future to be known as the Thomas Coram Schools, Berkhamsted.

Reports of Societies

PREPARATION OF DIABETIC PATIENTS FOR OPERATION

At the meeting of the Section of Anaesthetics of the Royal Society of Medicine on May 4 Dr. George Graham read a paper on "The Preparation of the Diabetic Patient for Operation."

Diabetes to-day, said Dr. Graham, was not a contraindication for any operation provided a physician was at hand who knew how to look after these patients, adequate facilities for such estimations as blood sugar were available, the best anaesthetic was chosen and given by a good anaesthetist, and the operation was well and quickly done. A local or spinal analgesic caused least disturbance. Gas-and-oxygen was the next best, provided enough sugar was given to prevent any cyanosis. The intravenous anaesthetics, pentothal and evipan, came next. Ether, which might be necessary to get complete relaxation with gas-and-oxygen, should be used only in small amounts; avertin was better not used, and chloroform should never be used.

The diabetic condition should be as well controlled as possible. If it was mild and the patient was not taking insulin but was having a small amount of carbohydrate, say, 100 g., it was better to increase the carbohydrate to, say, 150 g. and to give a small dose of insulin (10 units for an extra 50 g.). In the morning six units might be given, and four at night, for two or three days before operation. If the patient was having insulin but was passing a good deal of sugar, and the operation was not an emergency, it was better to increase the insulin for a few days, and thus stabilize the condition. If the patient belonged to the class liable to have overdoses when any attempt was made to get the urine sugar-free, no change should be made. The ordinary or quick-acting insulin should be used in the preparation of the patient rather than the slow-acting insulins. If the patient was taking one dose of protamine zinc or globin insulin, say 20 units, he should be given for two or three days 12 units in the morning and 8 at night of the ordinary insulin. If bigger doses were being taken they should be split up in the same manner.

On the day of operation the morphine given should be as small as possible, say 1/6 gr. The patient should have his usual feeds at bedtime, and on the morning of the operation he should have at least 50 g. of glucose. The dose of insulin given varied according to the type of anaesthetic. If 50 to 70 g. of carbohydrate were taken at breakfast the patient should be given 50 to 70 g. of glucose, and his usual dose of insulin, together with a supplement depending on the anaesthetic. If the anaesthetic was gas-and-oxygen and ether at least 10 units should be given as a supplement; if pentothal, 2 or 4 units; and if a local or spinal analgesic, no supplement at all. The sugar should be given two hours before the time for the operation. The only complication which might occur, if the dose of insulin and sugar was arranged somewhat on these lines, was hypoglycaemia, evidenced when the patient did not recover consciousness at the right time after the operation. Dr. Graham had seen this once only, but it was a complication to remember, and if the patient had not recovered consciousness at about the right time an intravenous injection of glucose should be given.

In an emergency operation, if the patient had been taking insulin and was not passing sugar, the dose of insulin and glucose was decided as for the set operation. If the patient was passing a good deal of sugar and some acetone bodies the supplementary dose of insulin for the analgesic should be increased—10 units for a local or spinal anaesthetic, 14 or 16 for pentothal, and 20 to 25 if ether was given. This supplement would be sufficient for the anaesthetic, but the patient might need much more after the operation. If he was very ill, with, say, intestinal obstruction, and passing much sugar and acetone bodies, and the operation could not be delayed, the dose of sugar should be increased to 100 g. and 100 units of insulin should be given. It was in this type of case that estimations of blood sugar were most valuable both before operation to ascertain the height of the blood sugar, and after to learn the effect of the anaesthetic. The patient would need big doses of insulin after the operation if coma was to be prevented, and it was a great advantage if the blood sugar could be estimated at frequent intervals.

Correspondence

Carbachol and its Antidote

Sir,—In the annotation on carbachol and its antidote (May 5, p. 636) the statement that atropine is an effective antidote against carbachol poisoning requires qualification.

Atropine will antagonize the muscarinic actions of carbachol, but requires more time to do so than it does to neutralize those of mecholyl. The reason for this is probably that carbachol is not affected by cholinesterase. Furthermore, atropine cannot block the nicotinic action of carbachol on ganglia, which action is relatively feeble in the case of mecholyl. In the case of the muscarinic action there is probably a quantitative factor, and the dose of atropine required increases to some extent with the dose of carbachol. It would therefore seem that to be sure of effective action of atropine against moderate doses of carbachol the former drug would have to be injected before the latter. The nicotinic actions would be left untouched.

When, by mistake, the dose of carbachol given is of the order of two hundred times the therapeutic amount the patient exhibits often a phase of severe hypertension. Carbachol is a useful, but none the less dangerous, drug, and should collapse occur following its use atropine is no certain guarantee of survival, although in many cases it will gradually relieve the collapse. Special caution in the use of carbachol is needed. The two unfortunate mishaps which have been reported as having occurred from mistaken injections of the iontophoresis dose instead of the proper subcutaneous dose would probably not have been averted by the use of atropine.—I am, etc.,

London, W.1. Hugh Dunlop.

Convalescent-home Accommodation

Sir,—In pre-war days it was commonly stated that there was a scarcity of convalescent-home accommodation for hospital patients of both sexes and all ages; so much so, indeed, that one often heard hospital almoners complaining of the great difficulty in obtaining convalescent treatment for patients about to be discharged from hospitals who were really unfit to return to their own homes and still less fit to return to their normal occupations. For this reason also many patients occupied beds in hospital longer than was necessary for hospital treatment, thus substantially reducing the annual turnover of beds, and consequently many patients were kept waiting much too long before admission to hospital. In other words, the hospital accommodation was not being used to the best advantage of the community, owing to the lack of suitable convalescent-home accommodation.

During this war considerable additions have been made to convalescent-home accommodation for the benefit of Service patients. For example, the War Organization of the British Red Cross Society and Order of St. John have at the request of the Ministry of Health provided more than 200 convalescent homes containing over 12,000 beds and more than 20 residential nurseries for delicate children under the age of 5 evacuated from London. These convalescent homes are scattered throughout the whole of England and Wales, so that every county has one or many more. They are mostly country mansions, adapted, equipped, and maintained, and (practically speaking) wholly paid for out of the Ministry of Health annual vote. Some are civilian convalescent homes at seaside resorts taken over by agreement for the duration of the war. Up to a recent date more than five million pounds has been paid by the Ministry of Health to the War Organization for the adaptation, equipment, and maintenance of these homes and residential nurseries.

All the convalescent homes and residential nurseries which I have visited are admirably adapted and well equipped for the purposes for which they have been provided, and there is no doubt they have been much appreciated and of immense benefit to the Service convalescents as well as the evacuated children under 5.

The time is now rapidly approaching when many of these convalescent homes will be closed down owing simply to the fact that the beds are no longer required for the convalescent Service patients or evacuated children, and ultimately of course the whole lot will be closed down when the last of the convalescent Service patients are discharged and the evacuated children under 5 return to their own homes. Bearing in mind the great shortage of convalescent-home accommodation in pre-war days and the very important fact that over five million pounds of public money has already been spent during the war on these "homes," it seems a thousand pities that, so far as I know, no attempt has been made by the Ministry of Health to arrange for these well-equipped places to be used for convalescent civilian patients from our hospitals after they are no longer required for convalescent Service patients and evacuated "children under 5." I fully realize that the owners of some of these adapted mansion houses and the management committees of the pre-war convalescent homes will desire their release as soon as conveniently possible, but it is equally certain that for obvious reasons a considerable number of the adapted mansion houses will never be occupied again by those families to whom they belong. In these circumstances surely it is worth while taking the necessary steps to secure the use of some of these well-equipped mansion houses for the benefit of civilian convalescent patients before they are stripped of their equipment and rendered useless for such a highly desirable purpose. The only authority in this country which can take the necessary action is the Ministry of Health, and it is devoutly to be hoped that the opportunity for securing this available and widely spread provision for the much-needed convalescent accommodation will not be lost.—I am, etc.,

Criccieth, North Wales. FREDERICK MENZIES, M.D.

Civilian Mass Radiography

SIR,—Your leading article on civilian mass radiography (April 14, p. 521) was of much interest to those of us carrying out the practical side of the work, but far from the apparatus being an interesting toy with a useful propaganda value the limited number of sets in operation are already performing a valuable function in the detection of the asymptomatic lesion.

There is no unanimity of opinion among the various local authorities and, need I add, among the interested members of the profession as to how these units should be organized. The problems of organization do not seem to be fully appreciated, and even with more apparatus diagnostic units or the more fully developed centres for clinical research are, for geographical reasons alone, except perhaps in exceptional cases, a practical impossibility.

Surely the fundamental function of a mass radiography unit is to detect an abnormality and, once detected, to pass the patient on either direct or through his own doctor to the appropriate and equipped centre for full and complete investigation—a procedure as suggested in Memo. 266T. As a separate centre for clinical research a whole team of medical personnel would be necessary, and it is not difficult to visualize that this promising infant would develop prematurely into a monster with bronchoscopy, electrocardiograph centres, etc., and before long special mass radiography hospitals.

In the mass radiography organization, unlike the Services, the attitude of the general practitioner must be considered, and it would be interesting to know whether, in a centre for clinical research, the patient's doctor is to play an active part or to be completely by-passed with or without even a letter informing him what action is being taken. In the organization of my own authority all persons requiring investigation are referred to their private doctor, as it is felt that the latter should be intimately associated with the general development of the scheme. I have heard it said and seen it stated in correspondence that this is the correct procedure; the following appeared in a letter in the *Journal* of Sept. 30, 1944: "The private medical attendant can best decide, on the basis of the report and his clinical observations, whether care and notification are necessary, or only an old lesion is being dealt with and secrecy can be maintained without danger to others."

During the past eighteen months the unit allocated to my authority has covered practically the whole of the County of London from eight static centres. Due in part to the specially abnormal conditions existing in London and the area surveyed, organization had to be somewhat different from that advocated in the M.R.C. report. No clinical work so far as the mass radiography unit is concerned is undertaken by the medical director. All full-size films are discussed by a panel comprising, apart from the medical director, the consulting radiologist for the council, a tuberculosis specialist, one general physician, and any tuberculosis officer in the area under survey who may care to attend. All individuals who in the considered opinion of the panel exhibit a significant lesion as judged by the skiagram, and a history, taken at the time of attendance for a large film, are referred to their own doctor with the *x*-ray films and report and suggestion as to further procedure.

Admittedly follow-up statistics and ultimate fate of individuals with minimal and other lesions are at a great disadvantage in the civilian unit as compared with the Services with their disciplined and organized population. The civilian is a free agent, and as he probably feels quite fit may elect to do nothing, remain under the supervision of his own doctor, or attend a private consultant rather than a tuberculosis dispensary. Information, however meagre, even on the immediate fate of these people is entirely dependent on voluntary co-operation, and I fully realize that an accurate follow-up over a period of years will be extremely difficult, if not impossible. But, however many the drawbacks, let us use mass radiography as, I believe, was the original intention—simply as a sieve to isolate those who need further investigation, leaving it to the existing services to complete the investigation and supervise these cases.—I am, etc.,

Public Health Department, L.C.C.,
London, S.E.1. J. STUART ROBERTSON.

SIR,—I have been greatly interested in the leading article on this subject and in the correspondence which has followed its publication.

The mass radiography centre of the Glasgow Public Health Department has, in its relation to tuberculosis, become in effect a sixth tuberculosis dispensary within the city. Its medical director has retained in his present post the facilities he had as a tuberculosis officer for observing patients in whom either the diagnosis of tuberculosis or the question of activity of a tuberculous lesion was in doubt, and for recommending patients directly for treatment or observation in hospital. Undue delay in admission of patients with early lesions to hospital is obviated, even in these days of long waiting lists, by his having a certain number of beds earmarked for the use of patients discovered by mass radiography. Patients are referred to the ordinary tuberculosis dispensary only after their dismissal from hospital or after a period of several months' observation at the mass radiography unit, if it is then decided that further follow-up is necessary.

It will be seen, therefore, that the patient does not require to go to the tuberculosis officer for the area in which he resides to obtain corroboration of the diagnosis. With this exception the administration of mass radiography in Glasgow is very similar to what Dr. Beynon has outlined for Nottingham in your issue of May 5 (p. 639), and the medical director here has the same close liaison that Dr. Beynon has with tuberculosis dispensaries, a cardiac clinic, the hospitals, and the bacteriologist.

I am definitely not in agreement with Dr. G. Lissant Cox (April 28, p. 605) in his view that the mass radiography team should leave arrangements for detailed diagnosis and treatment to existing chest clinics. This may be the most satisfactory administrative method for a county area, but it is certainly not required in large towns. In Glasgow it would add unnecessarily to the work of sadly overburdened dispensaries and *x*-ray departments. Further, is it not desirable that a patient who has probably paid three visits to the mass radiography unit, for miniature film, large film, and medical examination, should on the last occasion be given an opinion as to his condition and future treatment, and not have to undergo further review by another medical officer before a decision is made?—I am, etc.,

ALEX. MACLEAN,
Glasgow. Medical Director, Mass Radiography Centre.

SIR,—I have read the letters on this subject with interest and have been waiting for one of the "authorities" to come down to earth and discover that he is dealing with human beings and not a herd of animals. Except in a few cases each of these human beings has his own doctor of choice, who can probably give a full clinical history of his patient and would be of great help in assessing the case. In most cases, however, the patient's own doctor is ignored until the case has been passed from one "expert" to another and the patient's future has been decided upon.

I quote two instances from my own practice. I received a letter from the local mass radiography centre to say that as Mrs. A.'s miniature film was abnormal she had been recalled for a large film and clinical examination. A diagnosis of bronchiectasis was made, but the thoracic surgeon did not advise active measures on account of the general condition of the patient. On receipt of this letter I turned up my notes, and found that several years previously at my first examination I had written: "Bronchiectasis of both lower lobes, general condition poor, very nervous." In the second case Mr. B.'s miniature film was abnormal, and the letter from the centre runs: "I recalled him for a large film and clinical examination. When I did this I did not, of course, know that he had been in a T.B. sanatorium nine years ago." The man was examined and his B.S.R. done, and it was decided that there wasn't any marked activity at present. The patient had been examined at intervals by his previous doctor, by the tuberculosis authorities, and by me, and each one of us could—and did—reach this decision, and also could have prophesied what lesions would be seen in the radiograph. Both these patients thought they were bound to undergo all these investigations. It is true that they were asked to go, but we all know how requests from official sources can sound like commands. These are the only letters I have received, although probably several hundreds of my patients have undergone *x*-ray examination at these centres. It took me several weeks to allay Mrs. A.'s fears.

I freely admit that there may be a proportion of "missed" cases discovered by mass radiography; but I am sure that most of the "previously undiagnosed" discoveries are in people who had not been to their doctors for some time. Mass radiography can be a very useful weapon against pulmonary tuberculosis, but let us use it in the right way. May I, with the greatest trepidation, make a suggestion as to the routine to be followed in mass radiography? Mr. A. goes to be examined. His name and address are taken and he is asked if he has ever been treated for tuberculosis (the question can be worded in many ways to avoid the "T.B. complex" if so desired). The name and address of his doctor are entered on the record card. When the small film is examined the doctor is notified whether it is normal or abnormal. If abnormality is reported, surely it is entirely a matter for the patient and his doctor to decide what further action is to be taken. Further investigation can be made through the usual public health channels or privately at the patient's wish and expense.—I am, etc.,

Bristol. **Walter Woolley.**

Conservative Treatment of Tuberculosis in a General Hospital

Sir,—The present shortage of sanatorium beds has been the subject of much discussion and anxious thought on the part of those concerned with the treatment of pulmonary tuberculosis. It has often been found that during the time which usually elapses between diagnosis and admission to a sanatorium the patient's condition deteriorates, and he occupies a sanatorium bed for a longer time; or the consequences may be even more serious. It would seem that this evil cannot be overcome without more beds, yet much may be done to mitigate its effects. Where the prognosis is not hopeless when the patient is first seen, it is our experience that deterioration is rare, and improvement not unusual provided strict rest in bed is ordered and observed during the whole of the waiting period. In such circumstances collapse therapy is seldom a matter of urgency except in some cases of haemoptysis.

It is when the waiting period is spent in a general hospital particularly that the second danger is added. There too often the practice followed is recklessly to attempt to establish a pneumothorax without the knowledge, experience, and facilities necessary for the wise selection and management of cases and the recognition and treatment of complications. Much more harm is often done in this way than would have been the case had conservative treatment been adopted until admission to sanatorium was possible. To illustrate this point we quote our experience with the cases sent to us from one general hospital which has a distinguished medical staff:

Between September, 1944, and March, 1945, we received ten patients from that hospital, with one exception ex-Servicemen who were admitted there for treatment pending transfer to a sanatorium. In nine of them artificial pneumothorax had been embarked on there, and in seven quite clearly mismanaged. As a result the chances of recovery had been lessened in, at the very least, two, of whom one has died. Four of the seven, although in a precarious condition, had not been confined strictly to bed, and the patient who has died had been allowed home on week-end leave, although a month before spread of disease to the other lung had been noted. But the best example of the dangers of over-enthusiastic active treatment in inexperienced hands is provided by the following case. Pulmonary tuberculosis was discovered while the patient was a prisoner of war in Italy, and he spent a year in hospital in enemy hands, where he was treated on conservative lines. Repatriated last July, he was sent to that same general hospital, where a left artificial pneumothorax was induced. It was found that much of the upper lobe of the left lung, to which the disease was almost wholly confined, was directly adherent to the chest wall. At that stage the A.P. would have been abandoned by almost every physician with experience in that form of treatment and thoracoplasty contemplated. Instead the pneumothorax was maintained, and, worse still, ill-advised attempts at pneumonolysis resulted in haemothorax followed by tuberculous empyema and an atelectatic lower lobe, which is unlikely to re-expand. More recently the disease has spread to the other lung, and the prognosis is now hopeless.

We cite the foregoing series of cases because it illustrates so well the points we wish to make, and not because we think it is unique; in fact, though the twin bogies "air embolism" and "pleural shock" fortunately are seldom found outside the lecture room, the numerous common dangers may go unremarked in the medical schools. This appears to be a reasonable conclusion when such a note as the following accompanies a patient admitted here for adhesion section from a well-known teaching hospital: ". . . there were adhesions in the lower part of the thorax. About 300 c.cm. of air every three days has been necessary to maintain a *positive* pressure and to prevent expansion of the lung. . . ." The patient on admission was febrile, had a positive sputum, extensive adhesions at all levels, a turbid, sterile effusion, and a partially atelectatic lung.

Uniform success in the treatment of pulmonary tuberculosis attends none of us, but some of the bad results are not unavoidable. We feel that when we may expect the waiting lists to be swollen by the return of many tuberculous ex-prisoners of war we are justified in pleading that our medical colleagues, however distinguished in other fields of medicine, who have to treat these patients temporarily, should not be obsessed with what may seem urgent indications for collapse treatment, but more mindful of the importance of strict rest in bed, even in these days of acute shortage of nursing staff.—We are, etc.,

Artificial Respiration

Sir,—I do not want to take up valuable space in the *Journal*, but I do wish to point out that Schäfer's method has stood the test of time and experience and has given uniformly good results.

During the last year I have seen two young sailors who were subjected to underwater explosions when their ship was torpedoed. They were picked up in an unconscious condition by a trawler, some of the members of whose crew performed on them the mechanical method of artificial respiration advocated by Eve. The patients were transferred to hospital, and on their arrival at port their condition was desperate. One of the patients died two hours after admission, and necropsy revealed four perforations of the small gut with intestinal contents all over the abdominal cavity. The other patient recovered sufficiently to warrant surgical intervention. Laparotomy showed three perforations of the terminal ileum and one in the outer wall of the caecum. Although the perforations were small, the whole peritoneal cavity was full of faeces. The perforations were sutured, and all known methods to combat shock and peritonitis were instituted. The patient died two days later from general peritonitis.

There is not a shadow of doubt in my own mind that the "rocking method" of artificial respiration adopted in these two cases deprived these men of any chances of recovery. Medical men may employ any method of artificial respiration that they consider best, but is it justifiable to teach the lay public a method which is very dangerous under many conditions? The laity are not competent to diagnose surgical complications; and, therefore, any method of artificial respiration taught them should be simple and fool-proof and should have stood the test of time.—I am, etc.,

London, W.1. CECIL P. G. WAKELEY.

Sulphonamides in Measles

SIR,—The writers of the letters extolling the use of sulphonamides in measles appear to ignore the importance of controls in assessing the value of a drug. The score or so of cases I have seen in children in the recent epidemic were all treated by cutting off all food and drink except water, sugar, and fruit juice until the temperature was nearly normal. Some of them had expectorant cough mixtures, others sedative cough mixtures, and the rest no drugs at all, but this slight variation in treatment seemed to make no difference to the course of the disease. All the cases were as mild as those described by Dr. Frankland West (April 21, p. 567).

It may be that if sulphadiazine had been withheld from some of the cases described the course of the illness would have been more severe, but proof of such a theory is completely lacking.—I am, etc.,

Binfield, Berks. L. G. JACOB.

Oxaluria

SIR,—I was much interested in the article by Lieut.-Col. J. M. Black (April 28, p. 590) on the cases of oxaluria treated by him in India in 1943. He has rightly emphasized the importance of adequate fluid intake, and the avoidance of oxalate-containing foods in order to prevent oxaluria. There is one possible factor in oxaluria production which he has not mentioned, and which indeed seems seldom referred to in British medical literature, but which I have reason to think is very important. Prof. Herter in his *Lectures on Chemical Pathology* (1902) tells how his assistant, Dr. Helen Baldwin, produced oxaluria experimentally in dogs by giving them large quantities of cane sugar or glucose until a state of excessive fermentation accompanied by gastritis was produced, and gives it as his own opinion that "human oxaluria may arise during carbohydrate decompositions in the digestive tract under conditions at present imperfectly understood"—one of which may be "permanent diminution or absence of free hydrochloric acid in the stomach contents." My own experience in examining urines in the laboratory of this hospital leads me to think that this enterogenous formation of oxalic acid from excessive use of sugar, and perhaps even from excessive use of other carbohydrates, is far more common than is generally appreciated. Patients who are guiltless of partaking of such exogenous sources as rhubarb, spinach, etc., may show considerable oxaluria.

A case which came under my notice in May, 1944, may be of interest in this connexion. H. B., aged 48, a plumber in the employment of this hospital, noticed in March, 1944, that every evening after about 4 p.m. his urine became very red. His morning urine was normal in colour. This state of affairs continued for about three months, during which time he began to feel listless and lacking in energy, so that he became alarmed, and finally on May 4 presented himself at the accident dispensary of the hospital. He was cystoscoped, but no calculi were seen. Cystoscopy was again done on May 13, and a pyelogram taken, with negative findings. On account of his occupation he was sent to me for count of R.B.C., W.B.C., etc. There was no evidence of plumbism, but on examination of his urine I found oxalate crystals, as well as blood, present. I questioned him as to his diet, and found he was taking what seemed to me to be excessive quantities of sugar and other carbohydrates, as well as a good deal of strong tea. I advised him to modify his diet regarding these particulars, and gave him a little potassium citrate for a short period, asking him also to include a fair amount of ordinary vegetables (free from oxalic acid) and vegetable broths in his daily menu. After about four days haematuria ceased and has never since returned, and examination of urine on several occasions subsequently showed absence of oxalates, while his general health has returned to normal. It is true that his use of strong tea laid him open somewhat to exogenous oxaluria, but I think his excessive carbohydrates contributed largely to his condition. In the same way I would consider that the sugar content, no less than the cocoa content, of the chocolates used by Lieut.-Col. Black's patients is to be looked on with suspicion; oxalic acid might be formed from excessive sugar through sheer inability from any cause to oxidize glucose—to go no further with explanations. It is well known that diabetic patients frequently exhibit oxaluria. Neville's findings of oxaluria in cases of vitamin B deficiency are intelligible on this basis—oxidation of carbohydrates being necessarily slowed down under such a condition. Bacterial action is also a possibility in formation of oxalic acid from sugar.

I agree with Lieut.-Col. Black that it is useless to try to control oxaluria by reducing the calcium intake. Indeed, if sources of oxalic acid—exogenous and endogenous—are not avoided, reduction of the calcium intake may be a serious mistake, as in that case calcium may be abstracted from the bony framework in order to neutralize the oxalic acid. Oxalic acid, not calcium, is the primary sinner. But if oxalic acid for any reason tends to be introduced in excess, I would think it good therapy, in order to avoid formation of the insoluble calcium oxalate, to provide the system with a rational amount of sodium and potassium salts, which will tend to sweep away the oxalic acid in soluble form. A reasonable proportion of non-oxalic-acid-containing vegetables in the diet should help materially in this direction. Quite possibly the non-appearance of blood in H. B.'s urine in the morning hours was due to the well-known tendency of the system to be more alkaline after sleep and warmth. There may be, perhaps, some risk of running into the opposite danger of formation of phosphate crystals if excessive vegetables are taken, but all virtue, we are told, is a mean between two vices.—I am, etc.,

Royal City of Dublin Hospital. E. HARVEY.

Intravenous Pentothal in Placenta Praevia

SIR,—If Dr. J. Campbell (May 5, p. 642) reads the article by Majors S. O. Aylett and A. F. Alsop in the *Journal* of April 21 (p. 547) he will find that these surgeons describe pentothal as being "an ideal anaesthetic for abdominal operations in shocked patients." On the other hand, Crooke, Morris, and Bowler (*Journal*, Nov. 25, 1944, p. 683) prefer cyclopropane and oxygen, an anaesthetic which I also recommended in my letter. Evidently these latter observers are not favourably impressed with pentothal in cases where shock exists, which shows that experiences differ. Perhaps our favourable impression of pentothal in these exsanguinated cases can be accounted for to some extent by the glucose-saline which is given intravenously throughout the operation at the same time as the pentothal. Although the fluid administered in this way is probably beneficial, yet in those cases of retained placenta where shock is often present and manual removal is necessary pentothal is given without the saline; and so far we have seen no evidence in this institution that this form of treatment has been associated with increased shock.—I am, etc.,

County Maternity Hospital, Bellshill. S. J. CAMERON.

Barotrauma

SIR,—The correspondence on barotrauma has been followed with close interest. Some interesting discussions and important observations have been made. Whether one uses the term "otitic barotrauma," "tubo-tympanic pressure syndrome," "aural barotrauma," "anisobaric otitis," or, to keep in the fashion of mutilating the King's English, merely O.B., the fact remains that the condition is of great importance in aviation, both Service and civil.

I cannot agree that the condition is an inflammation, seeing that an acute inflammatory process is one which may proceed to pus formation. Such a sequel has not been reported, except when the area has been secondarily infected. Passive hyperaemia or congestion, yes; but inflammation, no.

It is interesting to note the percentages of visible auto-inflation mentioned by McGibbon. A recent survey of 2,500 cadets, who had been fully instructed in Valsalva's manœuvre and who had practised auto-inflation by this method before ascending to altitude in a decompression chamber, showed that only 32 (1.28%) had any subjective or objective symptoms of barotrauma. Those affected showed all the clinical stages of the syndrome: (1) Hyperaemia of the tympanic membrane with slight retraction relieved by auto-inflation at ground level (3=0.12%). (2) Moderate retraction of the membrane, hyperaemia of the mallear region with occasional small bullous formation in the posterior quadrant (21=0.84%). (3) Gross tympanic retraction, congestion of the membrane, serous or haemorrhagic bullae or exudate into the middle ear with residual deafness at ground-level (8=0.52%). No case of rupture of the tympanic membrane was observed.

It will be seen from these figures that auto-inflation by Valsalva's method, if correctly performed, is a reasonable prophylactic against barotrauma. The use of a Politzer bag while flying is excellent in theory but not in practice. Not only would it be an additional item of equipment, but it is not always successful, as may be seen when endeavouring to inflate the middle ear by politzerization in severe cases of barotrauma.

The answer to the problem is to avoid, so fâr as possible, the onset of the condition. This may be done by teaching aircrew (and passengers) the simplest effective method of auto-inflation and to "ground" anyone unable to ventilate the middle ear satisfactorily, whether due to barotrauma or to upper respiratory infection. If the condition should then arise and be diagnosed, the term "otitic barotrauma," although it may not be terminologically exact, does describe the syndrome and rolls off the tongue as easily as "tubo-tympanic pressure syndrome" or any other such designation.—I am, etc.,

M. E. GORDON, Fl. Lieut.

Newer Concepts of Breast-feeding

SIR,—I have read Dr. M. Witkin's article (March 31, p. 441) and the varying, though in most respects diametrically opposed, views of Dr. R. O. Barber (April 21, p. 566), Mr. Eric Coldrey, and Miss Isabel Wilde (April 14, p. 530) with interest. I consider satisfactory breast-feeding and any constructive aid thereto to be of paramount importance, and would like to put forward the following observations.

Taking only mothers who are keen to feed their babies, I would say that breast-feeding fails *(a)* because of "trouble" with one or both breasts, and *(b)* only in a minority of cases because there is insufficient milk. By "trouble" I mean primarily engorgement and the cracked nipple, the latter often being due to the baby being presented with an engorged breast which it cannot possibly "get on to" in the proper manner, this resulting in a chagrined chewing of the nipple which is sooner or later bound to produce a crack. I view engorgement as a complication which is unfortunately common, which is avoidable, and which ought to be avoided at all costs; I am certain the following regime does this and provides a sound approach to satisfactory breast-feeding.

The expectant mother should be shown by some competent person how to express her breasts, and she should do this twice a day for at least the last fortnight of her pregnancy. This prevents the ducts getting blocked by inspissated secretion, and, if an emollient such as arachis oil be used, keeps the areola and nipple pliable. I am assuming that the days of the nail-brush, however soft, and the bottle of methylated spirit are dead and gone for ever. I would like to insert here my abhorrence of such "hardening" agents as the much-used tr. benz. co. in the treatment of cracked nipples; I have found ung. hydrarg. ox. flav. excellent for this purpose, it being both an emollient and a mild, bland antiseptic.

Next, I am quite certain that both breasts should be used at each nursing. Five minutes at one breast, ten minutes at the other, then finishing with a further five at the original breast I consider to be the ideal arrangement. Dr. Barber states that "it is not until the babe has been to the breast for two minutes that the milk begins to flow": this just is not true. I can state as a fact that, if questioned, three out of every five nursing mothers with breast-feeding established experience what is termed (at least by the ladies of Lambeth) the "draught"—that is, the feeling of the breast filling up and in many cases the passive secretion of quite copious quantities of milk at times when the babe is due to come to the breast. In view of this I firmly believe it wrong to empty one breast and leave the other.

One problem I have often encountered is when the babe for some reason (e.g., after a difficult forceps delivery) is not considered fit to be taken to the breast for forty-eight hours or so after delivery. How often are the wretched mother's breasts left unattended for these forty-eight hours, with resulting engorgement and the sequelae depicted above? In such cases both breasts should be expressed at such times as the babe will be coming down, so that when it arrives it finds soft, pliable breasts with milk secretion, partially at least, already established, instead of a pair of hard, hot, painful balloons.

I disagree with Dr. Coldrey if by his concluding paragraph he infers that he says to his mothers: "Here's your babe, now feed it." Breast-feeding is, I know, a natural biological and physiological function, but the ignorance of most primiparae is immense, and I think it is a matter which, if we are to increase our most unsatisfactorily low percentages of fully breast fed babies, needs a very great deal of skill, patience, and experience.—I am, etc.,

St. Thomas's Hospital. MICHAEL PALLOT, D.R.C.O.G.

Women in Labour

SIR,—I feel that a sense of proportion must be reached in endeavouring to make labour painless. There is a danger, partly due to the publicity campaign for analgesia and partly due to labour being made to appear more pathological by insisting on hospitalization, that labour will become more painful, and therefore will require more analgesia. I am, personally, very insistent upon analgesia being given where necessary, but I feel that there is less required where the patient has been prepared by a calm conduct of the antenatal period. The power of the mind on sensitivity to pain is very strong, and, incidentally, too much "fussing" antenatally can make a patient apprehensive and therefore more sensitive to pain. It would be an advantage if, in the hearing of the mothers, the term "contraction" were used instead of the word "pain," the usual reference to "good pains" being calculated to upset a certain number of patients.

I fully endorse Dr. Florence McClelland's view (April 28, p. 607) that there is no universal analgesia for every case, and agree that a resident anaesthetist should be included on the staff of maternity hospitals. If hospitalization is to become the routine—and in view of the lack of home helps I feel that it is a necessary evil—the accommodation in hospitals must be radically altered. Every maternity hospital should have one or more "first-stage" rooms, so furnished that there is an atmosphere of a home and not the stern barrenness of hospital. By this I mean no tiled walls, many comfortable chairs, and recreational interests. There is no more distressing case than the patient who comes into hospital too early in labour and who has a prolonged labour solely due to the psychological inhibitions of hospital atmosphere on the uterine contractions.—I am, etc.,

Liverpool. JOHN HAMILTON.

Institutional Maternity Service

SIR,—Dr. Laura Hutton (May 5, p. 639) has made a useful contribution. There can be no question that "hygiene and asepsis have been allowed to outweigh all else in the modern development of maternity technique." She has done well to raise the issue of neonatal psychology. I venture to make the following observations.

1. The more we get away from the natural and the obvious, the more do we encourage an artificial attitude towards motherhood. Our changing social life may make institutional maternity frequently, or even generally, desirable, but let us refrain from pretending that this is a progressive step for which no price has been paid. We are converting an experience of rich emotional possibilities into a cold-blooded surgical episode, and we have no right to do so unless the change can be justified by convincing statistical proof rather than mere scientific theory. So far such proof seems to be lacking.

2. Breast-feeding is favoured and indiscriminate artificial feeding discouraged by all the highest authorities. Their grounds for doing so are chiefly physiological. But the psychological benefit to both mother and child is no less important.

3. The vogue of "rolling new-born babies into tight little mummies" is neither confined to institutions nor is it new. Swaddling clothes have been used for thousands of years and are still used in many countries. Dr. Hutton is no doubt correct in her psychological interpretation of the effect. But it seems to me that this also is a question of discrimination. The baby with an aggressive temperament will endure much environmental stimulation without damage to character development. He should be free from the beginning. But the infant of sensitive and apprehensive temperament needs security first of all. The mother's arms are the natural agents of this security. Failing them, I am prepared to believe that such infants benefit from habitual constriction—of course within

physiological limits. But it is to expect too much of nurses and mothers to base a technique on such close observation and fine differentiation. Let us not, however, accept either system—free or swaddled—as an invariable rule or as a universally progressive step.—I am, etc.,

London, W.1. H. CRICHTON-MILLER.

Organization of Research

SIR,—The letter by Dr. G. Arbour Stephens (April 14, p. 535) implies that there is considerable risk that anyone who does original work may lose credit for it by submitting it to a central organization. In practice, however, most original work has to be disclosed, in its early stages, to one of the bodies that finance research. If the filtering of ideas is to be feared under these circumstances, I have not encountered an instance in twenty-one years of full-time research. In practice I have always found that research workers discuss their ideas readily among themselves, without any thought of ulterior motives. Undoubtedly there is a standard of honour in such matters that gives the best possible protection against unjust claims.—I am, etc.,

P. R. PEACOCK,
Glasgow Royal Cancer Hospital. Director of Research.

Social Study of Hospital Treatment

SIR,—My attention has just been drawn to the interesting account by Dr. Malcolm Brown and Mrs. Freda Carling April 7, p. 478) of the after-care of patients who had attended the Radcliffe Infirmary.

The medical care of the discharged hospital patient, as the Oxford survey shows, is of such importance to-day that your eaders may be interested in a similar study, though wider in cope, undertaken by the Syracuse University College of Medicine in the United States. The study was initiated in July, 1940, and involved all patients discharged from the medical wards of the University Hospital up to February, 1942. It was undertaken after a preliminary survey had revealed that 90% of the cost of service on the general medical wards at the University Hospital was for chronic illness, and that only a third of these patients were receiving satisfactory medical supervision after discharge.

The hospital appointed an "extramural" resident (Dr. Frode ensen) to familiarize himself with the medical aspects of these patients and relevant emotional, social, and economic factors, nd to continue the medical supervision of the patients in their homes after discharge. At the beginning of the experiment the hospital social service department assisted in the provision of social service, but it soon became manifest that the volume of this kind of work was far too heavy a burden on the already verworked hospital social service department, and a special ocial investigator was appointed (Margaret A. Thomas, M.A.). The number of patients involved was 902.

The main finding was that because of proper care in the home many patients could be discharged from the hospital earlier and ehospitalization was greatly reduced. The saving in hospital costs was about three times the cost of the experiment, or, viewed in another light, sufficient hospital facilities were eleased to permit the acceptance of several hundred additional patients. Of even greater importance was the better medical care received by the patients.

The story of this experiment was published by the Common Wealth Fund last year under the title of *Medical Care of the Discharged Hospital Patient,* by Frode Jensen, M.D., H. G. Weiskotten, M.D., and Margaret A. Thomas, M.A. Because of the demands of the military service for younger graduates in medicine, the programme was temporarily discontinued in 1942, but there is little doubt that the service will be continued as soon as conditions permit, not only because of its value to the patient but also because of the economic saving it effected.

It is interesting to note that this experiment in medical care as originally undertaken as the result of a teaching exercise introduced in the curriculum of Syracuse University College of Medicine in 1930. This exercise is still in effect to-day. At that time, because certain faculty members believed medical ducation was becoming too institutionalized and that there was o great a tendency to stress disease rather than the patient uffering from the disease, a programme was introduced into the undergraduate curriculum which placed on each student the responsibility of making a complete study of at least one patient who had been assigned to him during his service in the medical wards of the hospital. The study required the personal investigation by the student of the home and the living and working conditions of the patient, careful consideration being given to the hereditary, environmental, social, and economic factors which might play a significant part in the patient's illness or recovery.—I am, etc.,

MARGARET A. THOMAS.

Shall We Nationalize Medicine?

SIR,—In her criticism of my letter (April 14, p. 535) pointing out the possible advantages of a national medical service, Dr. Alcock (April 28, p. 610) implies that she is in favour of maintaining the *status quo.* The fact remains, however, that the public do, apparently, desire such a service, and as the doctors were made for the people and not vice versa it is difficult to see how we can deny them their wish. The point I wished to make was that if a national medical service is to be instituted, despite all arguments to the contrary, then it is incumbent upon us to see that the conditions are made as favourable as possible, and that the state of partial slavery which has hitherto existed is not perpetuated. I consider that limitation of working hours and the dissociation of surgery premises from the home should be insisted upon in any agreement with the Government.

With regard to the patient, I cannot agree with Dr. Alcock that he would be worse off than at present. From personal experience in five different counties of England I have come to the conclusion that the patients of a single-handed doctor are often greatly inconvenienced by such occurrences as the illness of the doctor or his prolonged detention at midwifery cases, etc.

I entirely agree that it would be most undesirable to curb a doctor's potentialities by unduly limiting the size of his practice and paying him a fixed salary. For that reason I would propose a basic salary, plus a capitation fee for each patient. As regards those men who really feel that they are not being true to their calling unless they are always on duty, I can see no serious reason why they could not be allowed to indulge in their most admirable desire.

I am not a pessimist, nor the cynic that Dr. Alcock implies, but I have seen a great deal of very real distress among the members of our profession; and I do think the time is ripe for us to realize that the desire for reasonable working conditions is by no means incompatible with the maintenance of high ideals and a deep interest in one's work. Whatever his youthful standards may be, there comes a time in almost every doctor's life when he is physically and mentally incapable of living up to them, and the sooner we confess that we are men and not supermen the better for everybody concerned. Let us give full scope to our potentialities by all means, but at the same time let us refrain from turning our lives into mere tests of endurance, which can end only in the dissatisfaction and pity of our patients and the distress of ourselves and our families. Martyrdom is a thing of the past, the age of common sense and moderation has arrived.—I am, etc.,

Blackpool. H. DAKIN.

"It Can Be Done"

SIR,—In 1943, when I published a paper urging the obsolescence of ether and chloroform in anaesthesia, much obloquy was poured on my head for suggesting the possibility of using anything else in "pitching destroyers" or "desert tents," etc. I was exceedingly interested to read Major Rex Binning's account of 120 abdominal operations with pentothal–cyclopropane in forward areas during the Middle East campaigns, published in the *Journal* of May 6, 1944 (p. 620), particularly as I had repeatedly offered to design a portable cyclopropane outfit for field use previously. I was further greatly interested to read the paper by Majors Aylett and Alsop (April 21, p. 547) describing 56 consecutive abdominal casualties anaesthetized with pentothal alone in the forward areas in the present campaign in Europe, with, I venture to suggest, an uncommonly low mortality rate.

I feel that these papers go far to vindicate the main theme of my paper in the *Lancet* of Dec. 11, 1943: "Ether is now best avoided wherever possible, and in future should be eliminated altogether from our techniques"; and to confound my chloroform-and-ether addicated castigators of the subsequent correspondence. May I heartily congratulate the authors of the above papers on their skill, their progressive attitude, and their determination to improve the technique of anaesthesia. *It can be done.*—I am, etc.,

Park Prewett Hospital, Basingstoke. F. BARNETT MALLINSON.

Nursing in the New Health Services

SIR,—Large posters declare the dearth of nursing service. The following remedies, among which "two-tier nursing" is the chief innovation, may commend themselves to the profession.

1. The sole passport required from applicants is a *sense of vocation.* Many young women seem in their element when nursing. They display a spirit of succour which finds a natural expression in tireless tender care and is absolutely reliable and trustworthy. But often, sad to say, this is lacking in hospital and nursing home alike. Is not this to be expected when the authorities put the emphasis on scholastic qualification and make the school certificate a *sine qua non*? Surely the indication is to welcome to the profession all who are "born nurses," whether endowed with scholarly gifts or no, and give them a corresponding training and status.

2. Entrants would then be sorted by their interviewer according to their scholastic standard into those without and those with school certificate. The former would only take a short course and become *assistant nurses,* while most of the latter would, presumably, take the long course and become *fully trained nurses.*

3. Definitions of training.

(a) Assistant Nurse

Although an innovation, this new rank is but equivalent to making a permanent peacetime feature of the "nursing auxiliary." Moreover, to those of us in the know, it is obvious that only by tapping some such additional sources can we recruit the numbers needed to implement proposed reforms like the reduction of the twelve-hour day. After a preliminary dozen demonstrations in first aid and home nursing, their training would be entirely practical. It would consist of twelve months' medical and surgical ward work, culminating in a *viva voce* examination. On passing this, they would obtain the certificate of qualified assistant nurse. During training they would have all their domestic needs free and be paid, say, £25–£50 a year as pocket money.

Status: They would continue in the less exacting hospital services and domiciliary nursing, receiving a salary starting at, say, £100 a year, with five-yearly increments.

(b) Fully Trained Nurse

i. Preliminary course: About six months would be spent in introductory study of elementary anatomy, physiology, hygiene, disease, healing, ward procedures, practical demonstrations, and ending with an examination.

ii. Two years' practical nursing: This would be an entirely practical and clinical course, to which the nurse could devote her undivided energy and enthusiasm, having completed her lectures already. It would include casualty, out-patient, and, mainly, ward work, but exclude theatre, apart from accompanying patients and watching a good variety and number of operations on, say, twenty-five of those she will nurse. Pocket money should be the same as that for the assistant nurse: say, £25–£50 a year and all domestic expenses found—namely, board, lodging, laundry, and uniform. The training would conclude with an examination mainly practical and oral. Their hospital record would, as with assistant nurses, be taken into account by the examiners.

iii. Status and salary. She would have the title of "fully trained nurse" and a salary starting at, say, £150 a year, rising with experience.

(c) Nursing Specialists

Postgraduate training would be required for more responsible or specialized branches of nursing—e.g., to qualify for such posts as ward sister, theatre sister, as well as midwifery, public health, fevers, tutor, etc. Remuneration would be at an appropriately higher rate.

(d) Male Nursing Personnel

Theatre orderlies: It is to be noted that theatre training would become a postgraduate concern in the nursing profession. Only the minority with a bent for the work would take it up as it was not compulsory. A sister would still run the theatre, but the routine work, including the job of clean-nurse, would be handed over to men—male orderlies. They have, by contrast with average women, a natural aptitude for technical and mechanical procedures and have proved a success where, as at the London Hospital, the system has existed for years.

Ward orderlies: In wards also there may well be a limited number of openings for orderlies in the heavier jobs and, particularly, in male urinary work and chronic defaecatory disorders. Now is the opportune time for standardizing male orderlies.

(e) Elimination of Waste on Ancillary Services

The time has come for saving the wastage of nursing personnel on such ancillary posts as laundry, linen, housekeeping, home-sister, etc., wherein nursing training and talent are superfluous and a domestic science qualification is wanted.

The foregoing proposals may appeal to the profession, and, it is hoped, to the General Nursing Council for early consideration. It is most encouraging to find a layman so influential as Lord Auckland pressing, in your issue of May 5 (p. 646), for a higher standard of practical training for nurses.—I am, etc.,

Bristol. A. WILFRID ADAMS.

U.C.H. and Sir William Gowers

SIR,—May I correct your correspondent, Mr. Herbert Brown, who in the *Journal* of May 5 (p. 645) writes: "At the time my hospital training began antiseptic surgery existed in only two London hospitals—University College and King's." Howse (later Sir Henry), to whom I was dresser in 1878, on his appointment as assistant surgeon at Guy's Hospital in 1870 went at once to Edinburgh to study under Lister. When he came back to Guy's he immediately adopted antiseptic methods for his patients there, and his fellow assistant surgeon, Davies-Colley, did the same. In 1874 Howse became full surgeon with sixty beds. Strict Listerism was enforced in all his wards, and by this time the other assistant surgeons at Guy's had adopted antiseptic surgery.—I am, etc.,

Oxford. W. HALE-WHITE.

The Services

Surg. Lieut. M. D. Dawson, R.A.N.R., has been mentioned in dispatches for great devotion to duty and fortitude in the care of the wounded while serving in H.M.A.S. *Australia.*

Surg. Cmdr. E. R. G. Passe and Surg. Lieut.-Cmdr. S. C. Suggit, R.N.V.R., have been awarded the R.N.V.R. Officers' Decoration.

Col. (local Major-Gen.) W. E. Tyndall, C.B.E., M.C., late R.A.M.C., has been appointed a D.M.S., and granted the acting rank of Major-General.

Capt. J. C. Portnuff, R.C.A.M.C., and Capt. S. McClatchie, I.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in Italy.

Capt. C. H. K. Daly, R.A.M.C., and Capts. B. Nair and D. N. Vora, I.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in the field.

The following awards and mentions have been announced in recognition of gallant and distinguished services in North-West Europe:

M.C.—Capts. H. I. C. MacLean and C. H. Watts, R.A.M.C.

Mentioned in Dispatches.—Brig. (Temp.) H. L. Garson, O.B.E., M.C., T.D.; Brig. (Acting) R. H. Lucas, C.B.E., M.C.; Col. (Temp.) B. J. Daunt, O.B.E.; Lieut.-Cols. (Temp.) J. C. Anderson, K. H. Clark, M. de Lacy, T D., A. W. Gardner, J. A. D. Johnston, M.C., H. B. Lee, W. R. Logan, T.D., and H. Sissons; Majors (Temp.) I. Aubrey, M.C., A. W. Box, D. A. G. Brown, T. J. Brownlee, J. A. Elliot, E. E. Evans, M. C. Fulton, M.C., I. C. Gilliland, J. M. Henderson, S. T. Henderson, J. Kerr, J. M. Leggate, W. R. McCrae, W. Michie, R. O. G. Norman, I. D. Paterson, G. F. Petty, S. F. Raistrick, N. L. Russell, L. B. Wevill, and E. G. Wilbraham, M.C.; Capts. I. H. Baum, C. J. Champ, J. Clark, F. W. Dickson, J. P. Gannon, H. L. Gardner, T. Gass, E. G. Hardy, G. F. Houston, R. T. Kiddie, K. Misch, A. B. Robertson, T. H. Sansome, G. D. Scarrow, and A. Young; Lieuts. R. A. Condie and E. J. Rogers, R.A.M.C.

DEATHS IN THE SERVICES

Surg. Rear-Adml. JAMES LAWRENCE SMITH, C.B., R.N.(ret.) died at Waterlooville, Hants, on April 28, aged 83. He graduated M.B., C.M. at the University of Aberdeen in 1883 and entered the Royal Navy in 1884. For his services (Suakim, 1884–5) he received the Egyptian medal with clasp, and the Khedive's bronze star, and he later attended Prince Henry of Battenberg in his last illness. He was promoted fleet surgeon in 1900, deputy surgeon-general in 1912, and surgeon-general in 1916. In the following year he was made an Officer of the Legion of Honour, and he retired in 1919, having then been a member of the B.M.A. for thirty years. Adml. Smith received the M.V.O. in 1898 and was created a Companion of the Bath in 1918.

Obituary

LAURENCE CHRISTOPHER PANTING, who died on May 4, was for many years a leading surgeon in Cornwall. He was born in Staffordshire in October, 1869, son of the Rev. Laurence Panting, and from Shrewsbury School went up to Balliol College, Oxford, with an open scholarship, in 1888. He took his clinical course at Guy's Hospital, where he held a number of resident posts after graduating M.B., B.Ch.Oxon in 1895. He proceeded M.D. in 1900, obtained the F.R.C.S. in 1909, and the M.R.C.P. three years later. Settling in practice at Truro, he was elected surgeon to the Royal Cornwall Infirmary in 1902. During the last war he was surgeon to the Anglo-Serbian Unit and then to the County of Cornwall R.N. Auxiliary Hospital. On returning to civil life he was appointed surgical specialist for West Cornwall under the Ministry of Pensions. Mr. Panting was also honorary consulting surgeon to the Newquay, the Fowey, the St. Austell, and the Helston Cottage Hospitals, and to the Cornwall County Tuberculosis Sanatorium. He joined the B.M.A. in 1905 and was chairman of the West Cornwall Division 1924–6.

GEORGE ALGERNON FOTHERGILL, who died at the age of 76 at East Grinstead, gave up medicine many years ago to work as an artist. He was educated at Leamington College, at Uppingham School, and at Edinburgh University, graduating M.B., C.M. in 1895. He began the study of art at Uppingham, and at Edinburgh gained first-class honours in practical anatomy, and a medal in histology from the Royal College of Surgeons. During the latter part of the last war he served as M.O. of the 1st Cavalry Brigade at Aldershot with the rank of temporary lieut., R.A.M.C. Dr. Fothergill was an all-round athlete in his youth, and many of his pictures illustrated sporting subjects. He became well known as a painter in water-colour, a pen-and-ink draughtsman, a lithographer, and a designer of book-plates. His *Stones and Curiosities of Edinburgh and Neighbourhood* was illustrated by himself, and he published a number of essays, poems, and drawings. He exhibited at the Royal Scottish Academy, the Walker Art Gallery, Liverpool, the Leeds Corporation Art Gallery, and the Dudley Gallery in London. His collection of lithographs, engravers' proofs, etc., was acquired by the Corporation of Darlington.

Dr. WILLIAM BARBER BUTLER, formerly of Hereford, died on May 2 in retirement at Beaulieu, Hants. He studied medicine at the London Hospital, where he won scholarships in anatomy, in physiology, and in medicine, and qualified M.R.C.S., L.R.C.P. in 1894. Before settling in Hereford he had been resident accoucheur and house-physician at the London Hospital. He served for many years as surgeon to the Hereford General Hospital and Dispensary and retired from practice in 1929. He joined the B.M.A. in 1908, held office as honorary secretary of the Worcester and Hereford Branch in 1922–8, and as chairman of the Hereford Division in 1923–4.

Major GEORGE LEVERSTONE ALLEN, M.A., registrar of the School of Physic, Trinity College, Dublin, died on April 29, within a week of his eighty-eighth birthday. It was characteristic of him that he was at work regularly in his office in the School until two months before his death, and that he then left his desk with the greatest reluctance. It is given to few men to work hard and continuously for over seventy years, but Major Allen was an exceptional man. He enlisted in the Army when he was seventeen, and, after some years in the ranks, was commissioned in the Army Medical Service as a lieutenant (quartermaster). He saw service in almost all parts of the world and retired with the rank of captain in 1912, but was recalled during the last war and finally retired in 1918 with the rank of major. In 1913 he was appointed assistant registrar, and in 1926 registrar, of the School of Physic. He was distinguished physically for his activity and erect carriage and mentally for his wonderful memory and scrupulous accuracy. Until very recently his beautiful handwriting showed no trace of tremor. His urbanity was seldom ruffled, and his courtesy and willingness to help were extended to all who entered his office, from the most senior member of the staff to the most junior student. He knew every student who passed through the School and was respected and loved by them all. His colleagues will miss his experience, knowledge, and wise guidance. His passing will be mourned by the staff and students of the School and by medical graduates of Dublin University scattered over the world.—J. W. B.

Medical Notes in Parliament

Infantile Paralysis Outbreak in Mauritius

Col. STANLEY reported on May 2 that an outbreak of infantile paralysis occurred in Mauritius in March and 1,071 cases were notified up to the end of April. The following steps were taken to deal with it. Medical and nursing staff were immediately lent by the Governments of Kenya, Tanganyika, and Uganda, while the authorities of Oxford University made available the services of Prof. Seddon, who went to Mauritius by air accompanied by a research specialist, Dr. MacFarlan, from the Medical Research Council, and a masseuse. A special orthopaedic hospital had been opened under Prof. Seddon's immediate supervision. Two medical officers lent by the Army and R.A.F. respectively were co-operating in research work. Instructional advice for the people of the island had been widely issued. The outbreak appeared to be abating. Cases for the week ended April 28 decreased to 20 compared with 280 cases notified in the week ended March 24.

Sale of Practices

On May 3 Mr. STOREY asked whether the Minister of Health had any statement to make on the sale and purchase of medical practices in relation to the Government's proposals for a National Health Service.

In a written answer Mr. WILLINK stated that the Government recognized, as indicated in the White Paper, that a case could be made for the total abolition of the sale and purchase of publicly remunerated practices, and particularly of practices conducted in publicly provided health centres. The Government also recognized, as indicated in the White Paper, that the abolition would involve great practical difficulty and was not essential to the initiation of the new service. The Government felt that firm decisions, dealing with the practical difficulties fairly in the interests of all concerned if sale and purchase were to be abolished, could be reached only after some experience had been gained of the working of the new service and all the relevant facts had been ascertained. The Government did not propose, therefore, to make any alteration in the present custom in the forthcoming Health Services Bill, but proposed that a full inquiry into the whole question should be instituted by a committee appointed for that purpose after the new service had come into operation and experience of its working had been gained.

Meanwhile, to remove any present uncertainty, the Government wished to make it clear that if the sale of practices as a result of the inquiry he had mentioned be abolished or restricted by law, doctors affected would receive all proper compensation, on the understanding that (as indicated in the White Paper) the new service could not be allowed, by itself increasing values, to increase the amount of compensation payable. The Government also recognized that, pending the inquiry, many doctors would be returning from the Forces and entering new civil practices under the existing conditions of practice exchange." They were anxious that these men and women should not be prevented or discouraged from doing so by inability to find purchase money, and were discussing with the profession how this could best be secured.

Penicillin Supplies

Mr. WILLINK told Mr. G. Griffiths on May 3 that there was not yet enough penicillin for all restrictions upon its use to be removed. Penicillin could not be supplied on a doctor's prescription either for insured or for private patients. It was available only through hospitals. In most cases it should be administered in hospitals by staff specially trained in its use. Supplies were sufficient for all urgent cases likely to benefit from such use.

Health and Food in India

Mr. AMERY told Mr. Sorensen on May 3 that the incidence of cholera in Bengal as a whole had during the past year been below normal. He had seen recent press reports of a cholera epidemic in Calcutta and had asked for a report. Smallpox had been not very greatly above normal and very much below the corresponding figure for last year. Malaria, which had been for some time above the average, had recently been improving.

In reply to Mr. Fraser on the same date, Mr. Amery said the food situation in Malabar and Northern Madras had given rise to some anxiety, but the Government of India had been able to alleviate the situation by internal movement of "foodgrains." The Government of Madras had introduced systems of rationing which were reported to be working satisfactorily. He had had no report of any epidemic of cholera in Madras.

Silicosis among Slate Miners

Mr. Tom Smith told Prof. Gruffydd on May 3 that the number of cases of underground workers in slate mines in North Wales certified by the Silicosis Medical Board for total disablement or suspension from the industry since Jan. 1, 1940, when these workers were first covered by the Compensation Scheme, was 85. As figures were only available from the beginning of 1940 and machines were in use before that time it was not possible to say definitely what the effect of machines had been on the incidence of silicosis. Wet drilling or other appropriate methods of allaying dust had now been adopted in place of dry drilling. These and other precautionary measures being taken should in time result in a decreased incidence of the disease.

Returned Prisoners of War

In a reply on May 3 to Sir E. Graham-Little Sir James Grigg said prisoners of war returning from Germany underwent a full examination by a medical board during their leave. Any who were considered to be unfit for further service would be discharged on medical grounds. Those who were not recommended for discharge reported to a unit at the end of their leave where there were special facilities for examination by medical and other experts. Some prisoners would be sent to physical development centres to improve their physical condition, and the extension of these arrangements would, if necessary, be considered. Moreover the soldier's medical category would be subject to review in the light of his further progress. A returned prisoner would be retained in this country for at least six months, and thereafter he would be sent abroad only if a further medical examination showed that he was fit for this service.

Tuberculous Service Patients

On May 8 Sir Leonard Lyle asked the Secretary of State for War whether, in view of the increasing number of Service personnel who had contracted tuberculosis during their period of service, and who, in consequence, were discharged from the Service before they could be admitted to sanatoria, he would make a new regulation so that these men should not be discharged until at least eight calendar months had elapsed from the date of their first absence from duty on account of their disability. Sir James Grigg replied that until civil sanatoria were prepared to accept serving soldiers as patients he could not do what Sir Leonard Lyle wanted. This question was still being pursued.

Replying to further questions, Sir James Grigg said that these men had to be discharged because civil sanatoria would not take them as military patients. As soon as such sanatoria were prepared to take them as military patients the men could get exactly the same treatment as other soldiers. It was a question whether civil sanatoria could be persuaded to take them not as civil but as military patients. Dr. Summerskill asked why the Minister was not prepared to establish military sanatoria to remedy this injustice, and Sir James replied that, as Dr. Summerskill ought to know as well as most people, hospital accommodation had been arranged in this war in the main under an emergency hospital system and not a system of a series of military hospitals.

Colonial Medical Students in Britain

Colonel Stanley on May 9 assured Mr. Sorensen that there was no restriction on the number of West Africans who could apply for training in British medical schools and for training as nurses. Under war conditions, however, training institutions had been obliged to limit the number of Colonial medical students that could be accommodated. In regard to nurses, students had hitherto come to this country only by private arrangement, but steps were being taken to expand facilities for such training here. The number of West African medical students at medical schools in this country was understood to be 76 (including 12 Government scholars). There were also 11 medical students doing preliminary studies. There were believed to be about 10 girls being trained as nurses.

Married Women Doctors in E.M.S.

On May 10 Dr. Summerskill inquired whether the Minister of Health knew that under the conditions governing appointments in the E.M.S. a married woman doctor could not claim leave with pay on account of childbirth, whereas she was entitled to leave with pay on account of illness or accident; and whether he would take steps to remedy this injustice. Mr. Willink said he knew this. Married women enrolled as medical officers in the Emergency Medical Service were subject to the leave conditions applicable to all married women employed in the Civil Service in a temporary capacity. There would be no grounds for making a special exception in favour of E.M.S. officers.

Cost of Public Vaccination

Mr. Viant asked on May 11 what was the total cost of vaccination carried out during the Glasgow smallpox outbreak of 1942 and of vaccination carried out during the Edinburgh epidemic of the same year. Mr. Johnston replied that from estimates provided by the corporations of Glasgow and Edinburgh the principal items in the cost of vaccination during the smallpox outbreaks in question were:

		£
Glasgow:	Calf lymph, dressings, etc.	5,699
	Vaccination fees	10,469
		16,168
Edinburgh:	Calf lymph, dressings, etc.	5,944
	Vaccination fees	2,994
		8,938

He added that no Government grant was paid towards this expenditure, but lymph to an estimated value of £5,927 (not included in the figures above) was supplied free through the Government Lymph Establishment.

Smallpox at Indian Airfield.—Sir Archibald Sinclair stated on May 2 that recently there had been an outbreak of smallpox in India at an airfield used by transport aircraft. For their own protection and that of others Service personnel were not allowed to proceed by air to this airfield unless they had been vaccinated shortly before. Vaccination was, and remained, voluntary, and no one had been vaccinated against his will.

Hospital Beds.—Mr. Rostron Duckworth inquired on May 3 whether, in view of the cessation of enemy air attacks, the beds in hospitals reserved for potential casualties would be at once returned to ordinary civil use.

Mr. Willink answered that the beds now reserved in certain hospitals in the Emergency Hospital Scheme were for all classes of patients for whose treatment he was responsible, including Service casualties and sick. No beds were specifically reserved for air-raid casualties.

Medical Advice in Military Detention.—On May 8 Sir James Grigg informed Mr. Turton that no soldier serving sentence in detention barracks was or had been released from so doing on the certificate of a psychiatrist alone. Medical advice, however, was one of the considerations on which the appropriate military authorities remitted or suspended sentences of detention.

Sickness among Bus Drivers and Conductors.—Statistics furnished to the Ministry of War Transport by the London Passenger Transport Board show during the year 1944 a sickness rate for central buses of 6.4% among drivers, 7.3% among male conductors, and 13.1% among women conductors. For country buses the equivalent figures were 3.3%, 6.2%, and 8.2%. For trams and trolley-buses they were 5.9%, 10.5%, and 17%. For railways under the L.P.T.B. the sickness rate for all operating grades was 6.7%.

Notes in Brief

Disabled men in receipt of 100% pension for total blindness arising out of the present war, including the Navy, Army, R.A.F., and Merchant Navy, number 300; for the last war the number was 1,800.

Mr. Churchill announced on May 10 that a basic petrol ration, freely at the disposal of private owners of motor-cars and motor-cycles, would be introduced in 30 days. An increased allowance would be given to cars and motor-cycles used for professional purposes.

Universities and Colleges

UNIVERSITY OF EDINBURGH

The Sixth Sharpey-Schafer Memorial Lecture, on "The Absorption and Excretion of Water, and the Antidiuretic Hormone," will be delivered by Prof. E. B. Verney, F.R.C.P., F.R.S., on Friday, June 8, at 5 p.m., in the Anatomy Class Room, University New Buildings, Teviot Place, Edinburgh. All interested are invited to attend.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

The Council has decided to institute monthly subscription dinners in the College for Fellows and Members of the College and members of the specialist associations linked with it through the Joint Secretariat. They will be held on the evening of the Wednesday preceding the second Thursday of the month, and the first of the series has been arranged for Wednesday, June 13. Applications will be dealt with in the order in which they are received and must reach the Secretary of the College in Lincoln's Inn Fields, W.C.2, at least a week before the date of the dinner, accompanied by payment of the inclusive charge of £1 1s. for each dinner. The Council's object is to give those associated with the College opportunities of meeting socially more often. If it is found that the opportunity of dining n the College is much appreciated arrangements will be made for hese dinners to be held at shorter intervals. It is intended in the plans for restoration and development that facilities for lunching and dining in the College shall be greatly increased.

The following candidates were successful in the recent Primary Fellowship Examination conducted by the Royal College of Surgeons of England:

H. M. Bradmore, D. M. Brooks, W. Burnett, Muriel Crouch, M. P. Durham, . A. W. Edwards, V. G. Griffiths, S. W. G. Hargrove, M. Kaye, L. P. Le Quesne, A. B. McCarten, D. A. Macfarlane, Doreen Nightingale, K. W. E. Paine, A. J. Partridge, R. E. Renaud, J. M. H. Ross, H. O. Thomas, P. C. Watson, Margaret . Yeoman, J. Zimmermann.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

At a quarterly meeting, held on May 1, with the President, Dr. A. Fergus Hewat, in the chair, Dr. James Ronald (Stirling) was introduced and took his seat as a Fellow of the College. Drs. Cyril Hocken Tewsley, C.M.G. (Auckland, N.Z.), Munir El Gazayerli Alexandria), Bryce Ramsay Nisbet (Kilmarnock), Albert Arthur Huse (Birmingham), and Ronald Haxton Girdwood (Edinburgh) were elected Fellows of the College.

Prof. J. A. Nixon was appointed Dr. Alexander Black Lecturer or 1945.

ROYAL COLLEGE OF PHYSICIANS OF IRELAND

At a meeting of the President and Fellows of the Royal College of Physicians of Ireland, held on May 4, the following Members were elected Fellows of the College:

Vincent Cornelius Ellis, M.D., James Cyril Gaffney, M.D., Patrick Aloysius McNally, M.D., John Norman Parker Moore, M.D.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At the monthly meeting of the Royal Faculty of Physicians and Surgeons of Glasgow, with Mr. William A. Sewell, President, in the hair, Jane Hyslop Merry, M.B., Ch.B., was admitted a Fellow of Faculty *qua* Physician and William Malcolm Gibson, M.B., Ch.B., was admitted a Fellow of Faculty *qua* Surgeon.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* the chief features of the returns were an increase of 122 notifications of measles, and 70 of scarlet fever; dysentery notifications were down by 37.

Diphtheria notifications were maintained at the level of the preceding week; the local variations of note were increases in Staffordshire of 10, and in Worcestershire of 11, and a fall of 18 in Northumberland. There was little change in the returns for whooping-cough. The rise in scarlet fever was mainly due to increases of 60 and 20 notifications in Lancashire and London espectively. The notifications of measles were up in Monmouthshire by 152, Surrey by 134, Derbyshire by 130, Northamptonshire by 208, and in Lancashire by 89; they were down n London by 256, Southampton by 152, Gloucestershire by 140, and in Warwickshire by 118.

There were slightly fewer cases of dysentery. The largest returns were Lancashire 61, Gloucestershire 47, Kent 41, Staffordshire 40, London 32, Yorks West Riding 32, Middlesex 28, Warwickshire 15, Hertfordshire 12, Worcestershire 12, Suffolk 12, Devonshire 11.

In *Scotland* diphtheria was up by 18 cases, scarlet fever by 20, and whooping-cough by 20; there were 96 fewer notifications of measles, and 9 fewer of dysentery. But dysentery increased in Edinburgh from 30 to 53 cases, and in Aberdeen from 21 to 34; the other large returns were Glasgow 44, and Dundee 14.

In *Eire* small decreases were recorded for most of the infectious diseases, the chief exception being a rise of 13 for measles. Eight cases of typhoid were reported from Donegal, Glenties R.D.

In *Northern Ireland* the only changes in the incidence of infectious diseases were a rise in diphtheria of 8, and a fall in measles of 11.

Diphtheria among Canadian Troops

The Canadian National Defence H.Q. announced that an outbreak of diphtheria among Canadian troops on the Western Front reached a peak of 118 cases per 100,000 in January, and had fallen to 35 per 100,000 by March. The outbreak did not reach serious proportions, due to the Canadian Army's policy of compulsory immunization.

Week Ending May 5

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,351, whooping-cough 1,050, diphtheria 504, measles 13,139, acute pneumonia 518, dysentery 469, paratyphoid 7, typhoid 3.

No. 17

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended April 28.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

---

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

The following films will be shown by the Scientific Film Association, in the last programme of its present series, on Wednesday, May 23, at 5.30 p.m., and again at 8 p.m., at the Royal Society of Medicine, 1, Wimpole Street, London, W.: "Killing Farm Rats," "Rabies," "Microscopic Observations of Living Tissue," "The Effect of Thymectomy on a Case of Myasthenia Gravis," and "The Effect of Centrifugal Force on Fighter Crews." Admission will be by ticket only, and those who have not already done so should apply immediately to the honorary secretary of the Medical Committee, Dr. S. J. Reynolds, 14, Hopton Road, London, S.W.16.

A meeting of the Medico-Legal Society will be held at 26, Portland Place, W., on Thursday, May 24, at 5 p.m., when Dr. Edward Glover will read a paper on "The Social and Legal Aspects of Sexual Abnormality."

A meeting of the Clinical Society of the Royal Eye Hospital will be held at the hospital, St. George's Circus, Southwark, S.E.1, on Friday, May 25, at 5 p.m., when a talk will be given by Dr. T. H. Whittington on alternating strabismus.

The Royal Sanitary Institute (90, Buckingham Palace Road, S.W.) announces the following sessional meetings: At Swansea Guildhall, Saturday, May 26, at 11 a.m., paper on "Reconstruction and Housing Proposals of Swansea," by Mr. J. B. Bennett; at Usher Art Gallery, Lindum Road, Lincoln, Saturday, June 9, at 10.15 a.m., papers on "The Influence of Housing Needs on the Planning Scheme," by Mr. R. L. Stirling, and "The Water Undertaking and its Contribution to the Nation's Health," by Mr. D. Whiteley; at Royal Institution, Colquitt Street, Liverpool, Friday, June 22, at 10.45 a.m., paper on "Public Health and the Social Services," by Dr. C. O. Stallybrass. In the afternoon a paper on "Post-war Housing" will be read by Mr. L. H. Keay.

The British Orthopaedic Association is meeting at Horton Emergency Hospital, Epsom, on Friday, June 1, and Hill End (St. Bartholomew's) Hospital, St. Albans, on Saturday, June 2.

A meeting of the Medical Society of the L.C.C. Service will be held at the North-Western Hospital, Lawn Road, N.W., on Wednesday, June 6, at 3 p.m., when there will be a clinical and pathological demonstration of puerperal sepsis and gastro-enteritis.

At a Court of the Directors of the Society for the Relief of Widows and Orphans of Medical Men, held on April 11, with Dr. R. A. Young, president, in the chair, the audited accounts for the year ended December 31, 1944, were presented and approved. The chairman brought to the notice of the directors the following personal item of interest: The first secretary of the society, the father of the present secretary, held office for 37 years, and his son has been secretary for 40 years, making a combined total of 77 years' service. The society has been in existence for 157 years, thus the last two secretaries have held office for practically half that period. The annual general meeting will be held on May 23, at 5 p.m. A new list of members has been printed, and any member may obtain a copy on application to the secretary at 11, Chandos Street, Cavendish Square, W.1. Membership of the society is open to any registered medical man who, at the time of his election, is residing within a twenty-mile radius of Charing Cross. Relief is granted only to widows and orphans of deceased members. Full particulars may be obtained from the secretary.

Dr. Edwin J. Cohn, professor of biochemistry at Harvard University, has been chosen as the first recipient of the Passano Foundation award. The Foundation was established in 1944 by the Williams and Wilkins Company, medical publishers, of Baltimore, to aid the advancement of medical research, especially research that bears promise of clinical application. Dr. Cohn is distinguished for his work on the fractionation of blood. Beginning in 1919 with a study of blood and blood proteins his research has yielded a group of five principal fractions of blood plasma.

Sir Raphael Cilento, M.D., Director-General of Health and Medical Services for Queensland and honorary professor of tropical and social medicine in the University of Queensland, has been appointed to take charge of U.N.R.R.A. antimalarial work in the Balkans.

The Ex-Services Welfare Society (Temple Chambers, Temple Avenue, E.C.4) will hold its 9th Annual Medical Conference at the Waldorf Hotel, Aldwych, W.C., on Friday, June 1, at 10.30 a.m., under the chairmanship of Lord Horder. Important post-war problems will be discussed.

Miss Charlotte Purnell, O.B.E., M.S., who died on June 20, 1944, at Amman, Transjordan, aged 75, was for 20 years a medical missionary of the C.M.S. in the Near East, and later conducted an English mission hospital at Amman. By her will she left £1,000 for that hospital.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square London, W.C.1. Telephone: EUSTON 2111. Telegrams: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). Telephone: EUSTON 2111. Telegrams: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. Telephone: EUSTON 2111. Telegrams: *Medisecra Westcent, London.*

B.M.A. Scottish Office: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Pyelitis in Child of 2

Q.—*A well-developed infant aged 2 years had acute pyelitis 6 weeks ago. She was well in 2 days on sulphathiazole, which was given for 4 days in the hope of ensuring complete cure. She also had limited alkali. Nine months ago she had a similar attack, which responded to the same treatment. Now her urine shows a trace of albumin, a few pus cells, and B. coli. There is no external evidence of congenital deformity. Can I try a further course of sulphonamides and alkali before G.U. investigation? Is sulphamerazine the most suitable? If so, how much, and for how long?*

A.—In view of the short period of treatment given for the last attack it would be worth while to try a longer course before resorting to other measures. There is not enough information about the action of the newer sulphonamides on urinary tract infections to lay down any hard-and-fast rules about the choice of drug, and in any case different strains of organism vary in their sensitivity. A *B. coli* infection will usually respond to sulphanilamide, and, where this fails, sulphathiazole may succeed. A dose of 0.25 gramme of either drug 4 times a day should be adequate for treating a urinary tract infection in a child of this age: this treatment should be continued for a week, and alkali, as suggested, should be given in addition.

Analgesia in Midwifery

Q.—*What is the best and safest method of ensuring analgesia in midwifery? Recent discussion on this point has left me in rather a haze.*

A.—Although there is still no completely satisfactory analgesic for use in midwifery, there are several which are reasonably effective and safe. The results obtained with each method depend to a large extent on experience in their use, and each observer tends to adopt some particular method and to become expert in modifying it to suit individual cases; hence the various claims and opinions expressed. For the first stage of labour the older analgesics—morphine (with or without hyoscine) and chloral and bromide—still deservedly retain their popularity, although many barbiturates, such as nembutal, pernocton, seconal, are employed as alternatives. Neither morphine nor barbiturates, however, should be given within four to six hours of the birth of the child, and should therefore be used with caution in multiparous patients in whom labour is progressing rapidly.

Of the newer methods I would suggest that the inquirer try pethidine, 100 mg. intramuscularly, together with seconal gr. 1½, or scopolamine gr. 1/150, to be given when the cervix is about two fingers dilated. The dose of pethidine can be repeated in two or three hours if necessary. For details on the use of pethidine reference should be made to three articles in the *Journal*: 1944, **1**, 176, 179; **2**, 498. For analgesia at the end of the first stage and during the second stage of labour gas and air, administered by Minnitt's or other similar apparatus, still has the first claim for consideration from the standpoint of safety, non-interference with the progress of labour, analgesic properties, and relative simplicity. But again some experience in its use is necessary before the best results are obtained.

Breast Milk and the Diet

Q.—*Is there any scientific proof—as distinct from midwives' superstitions—that certain substances in normal household diet (particularly fruits and vegetables, tea and coffee) and common laxatives (e.g., phenolphthalein, senna, or cascara) have any deleterious, or indeed any pharmacological, action on the infant, when ingested by the lactating mother? To what extent, in fact, can the breast milk be modified in any direction by the mother's diet?*

A.—There are several interrelated questions here which can be dealt with under three headings:

(*a*) *The Secretion of Drugs in Human Milk.*—There is ample proof that this occurs. The late Eric Pritchard used to say that the mammary gland was not nearly such an efficient filter as the placenta, and, in consequence, drugs can get through more readily. The list ncludes arsenic, aspirin, bromides, mercury, iodides, salicylates, and, more recently, the sulphonamides. Of the alkaloids, morphine and atropine are generally included. Other substances vouched for are alcohol and nicotine. Observations have been made not only on he analysis of milk for these substances, but also for the effects on he infant.

(*b*) *Have such Drugs or Substances any Effect on the Infant?*—Bromides given to the mother will produce a rash in the infant as well as drowsiness. Organic arsenicals are said to have produced udden death. The relation between phenolphthalein given to the mother and green stools in the baby is seen sufficiently often to uggest cause and effect. But babies vary in their susceptibility. A test "dose" of sour fruit (e.g., unripe plums) to a ward of ying-in mothers will produce green stools in only some of the infants. Some lactating women can eat anything they like, even to the more exotic foods such as lobster, without any apparent trouble in the baby. Others have to be more careful, as certain articles seem to cause infantile upsets. The same would appear to apply to common axatives.

(*c*) *Modifications in Composition of Breast Milk.*—As regards the average percentage of the main constituents of milk, little can be done to alter them by diet. Indeed, even starvation seems to mean only less milk, not a qualitative alteration. The superstition about he milk being "too weak" (not confined to midwives, but widespread among doctors) dies hard. Total solids vary very little. Occasionally, an over-fat milk can be rendered less rich by reducing he mother's fat intake. But the constituents other than protein, fat, and carbohydrate—i.e., the minerals and vitamins—probably do vary and can be varied according to a mother's diet.

Calciferol and Toxisterol

Q.—*Does toxisterol exist, and if so, does it occur in the natural sources of vitamin D, such as cod-liver oil?*

A.—Toxisterol does exist. It is one of the many sterols formed by irradiating ergosterol with ultra-violet light. The first product of irradiation is calciferol, which by further irradiation is converted into lumisterol, tachysterol, and toxisterol. Over-irradiation of ergosterol produces toxisterol. Toxisterol does not occur in cod-liver oil and natural sources of vitamin D. As its name implies, it produces toxic reactions and has a low antirachitic potency.

Psychological Causes of Insomnia

Q.—*On Sept. 30, 1944, p. 458, a question was asked about nembutal for sleep. The reply stated that this was practically innocuous, but that it did not get at the causes of insomnia. I wonder how tranquillity can be obtained by those of us who throughout our lives have worried unduly—or perhaps not unduly but enough to prevent sleep.*

A.—The most common psychological cause of insomnia is, of course, that one has "something on one's mind"; in other words, it is due to the perseveration of some unsolved problem (reference may be made to the reply on sleep-walking, *B.M.J.*, Jan. 27, 1945, p. 139). In ordinary and sporadic instances of insomnia, such as most people suffer from on occasion, it is best to wake oneself right up, if not fully awake already, and ask oneself what one is worrying about. Even if we cannot solve it at the moment we may at any rate see what it is and defer solution till the morning.

But most insomnia is not so simple as that; for the mind tends to push away unpleasant things and may succeed in doing so, entirely repressing and forgetting them. At night, the worry returns when our vigilance is relaxed in sleep. The clearest instance is that of people who wake up at a certain time every night, say at 3 a.m., irrespective of external stimuli. This is always found on analysis to be due to the fact that at that precise moment the patient once had some unpleasant experience or problem: one man wakened to find he had dysentery; another to realize his wife no longer cared for him. We go to sleep to escape the problems of the day; we wake up to escape the problems of the night.

The link between the physiological and psychological is instanced in what we may term psychosomatic insomnia: worry affects the gastric secretions and produces indigestion, and the indigestion produces the insomnia.

Chronic insomnia is usually due to the persisting problems and worries of our lives which we repress, and of which we are unaware. It is in fact precisely of the same nature as neuroses and must be regarded with the same seriousness as disorders like agoraphobia, requiring radical treatment. In such cases we are unaware of the object of anxiety, and tend to transfer our worry to insignificant things; or, because we cannot sleep, this anxiety gets transferred to the sleep itself, and we begin to worry whether we shall sleep or not; and that worry then appears to be the one which keeps us awake, and a very real worry it is. But the fundamental trouble lies deeper, and needs thorough psychological investigation. Perhaps the most common cause is where there have been dreads and fears in early childhood, say from illness, against which fear an attitude of self-sufficiency, success, ambition, and achievement is set up *as a barrier*. So urgent is it to get on that the personality is in a perpetual state of strain and tension. The investigation and treatment are usually long, but if successful are preferable to being doped all one's life.

Short of radical treatment, a form of self-hypnosis is often valuable—namely, with eyes closed, and slightly turned upward, to gaze fixedly at one of the spots or lights from the retina, and whenever our attention wanders to bring it persistently back. Hypnosis is essentially a phenomenon of attention, and if we can keep our attention fixed on the spot by effort of will, we exclude the worry and by tiring our attention go to sleep. But persistence is very necessary.

Peat Baths

Q.—*Are there any spas or other places in this country where peat baths are given as I have seen them given abroad? Is there any firm that prepares peat for home baths?*

A.—Peat baths are given in this country on an extensive scale at Buxton, Harrogate, and Strathpeffer on the same lines as at Continental spas. It may be of interest to mention that Dio Cassius, writing at the time of Tacitus the Roman historian, records that the Picts used peat baths on primitive lines, presumably for the treatment of rheumatism induced by the climate of our islands, so that originality in the use of the method does not belong to the Continental spas. So far as the writer is aware no firm supplies peat prepared for baths; it would probably be expensive and unsatisfactory without special arrangements for heating the peat.

Record Number of Caesarean Sections

Q.—*How many Caesarean sections for pelvic disproportion may be safely carried out before sterilization must be done to prevent the danger of future pregnancies? Is there any available information on the "record" number of Caesarean sections carried out on one patient?*

A.—Each Caesarean section entails the ordinary risks of a major operation. When the operation is repeated the likelihood of adhesions increases, the abdominal wall becomes scarred and weakened and so does the uterine wall—involving danger of ruptured uterus in a subsequent pregnancy. The occurrence and importance of these factors vary in different patients, so the number of operations which can "safely" be carried out also varies. Apart from the question of safety, the wishes of each patient should be carefully considered in reaching a decision—as should other factors, such as whether the other children have survived. Most women consider—and their views are supported by most obstetricians—that when they have suffered the discomfort, inconvenience, and risks of three operations they have "done their duty," so sterilization is usually carried out at the third section. But this is a practice based on general principles and experience rather than any absolute indication, and need not be adhered to strictly in any given case.

Five or six Caesarean sections on the same patient are not very uncommon, but the published "record" appears to be held by the patient whose ninth operation (eight upper segment and one lower segment) was carried out and reported by D. J. McSweeney (*Amer. J. Obstet. Gynec.*, 1940, **39**, 155). She had also had two other abdominal operations—appendicectomy and cholecystectomy—yet at the time of the ninth section, and at the age of 38, she asked not to be sterilized because she was anxious for further children. However, by the time she was 45 there had not been any more pregnancies. According to McSweeney the previous highest number recorded was seven.

X Rays for Perionychia

Q.—*Is there any satisfactory treatment for (non-purulent) perionychia of the fingers?*

A.—Perionychia often responds to small doses of *x* rays, say 50 *r* (180 kV, H.V.L.=1.0 mm. Cu) every fifth day for six weeks.

Treatment of Warts

Q.—*There appears to be a large increase in the incidence of warts. The treatment recommended varies from x rays to nitric acid and incantations. I shall be grateful for suggestions for rational treatment of a case which, in spite of local applications and x-ray treatment, is still extremely painful to the small girl who is suffering from it. Is the condition contagious?*

A.—It is assumed that the wart is on the sole, where treatment is made more difficult by the thick horny layer in which the wart is embedded. A 20% salicylic acid plaster applied exactly to the wart—and removed from time to time—held in position by elastoplast, often succeeds. Local analgesia and the curette are also effective, or prolonged freezing with CO_2 snow may be tried; this, however, requires practice and experience. The condition is probably contagious, the bathroom floor and mat providing the link.

Prognosis in Hodgkin's Disease

Q.—*Does complete recovery from Hodgkin's disease ever occur, and if so, after what interval, during which the patient is free from signs and symptoms, can it be assumed to have taken place? If complete recovery is possible, in what percentage of cases does it occur?*

A.—There is no evidence that complete recovery from Hodgkin's disease ever occurs. About 80% of the subjects die within three years of the onset of symptoms, and only about 5% live more than five years. In any large series of cases there will be a few with a duration up to ten years, and survival for twenty-five years has been recorded. It is not possible to make an accurate prediction in the individual patient. Even though the patient has been completely free of symptoms for months or years, the disease may suddenly reappear in an acute and rapidly fatal form.

Intramuscular Injection of Iron

Q.—*In the treatment of microcytic anaemias, is there a physiologically effective preparation of iron for intramuscular injection?*

A.—No, there is not. Iron is one of those substances which are much more toxic by injection than by mouth, and the minimum effective dose (25 mg. Fe a day) is very close to the maximum tolerated dose. Immediately after the injection of this amount of iron the patient experiences unpleasant symptoms such as feelings of warmth, nausea, vomiting, palpitation, and precordial constriction. It is conceivable that a preparation might one day be found from which the iron is gradually released, as the active arsenic is released from neoarsphenamine, but the intense physiological activity of iron and the absence of channels of excretion do not make the prospect very hopeful.

LETTERS, NOTES, ETC.

Possible Contagiousness of Cancer

Dr. J. H. DOUGLAS WEBSTER (London, W.1) writes: The expert answering the question on this subject (March 31, p. 468), who says that "cancer is no more contagious than broken legs," seems to base this verdict (the orthodox one) on the observation that a chicken sarcoma does not spread to chickens in the same pen; and on the scepticism statisticians have about "cancer houses." But should not a distinction first be drawn between "closed" and "open" cancers? A cancer shut off in an otherwise normal organ (as breast or liver) cannot be contagious: but may not an open cancer (of skin, lip, cervix, or rectum) possibly be contagious? In patients occasional infection of the opposite lip or labium has been observed; and infection of an abdominal or breast scar during operation (as in a stitch-hole) has often been noted. Patients with skin cancer sometimes apparently infect themselves by scratching: I have now a patient with multiple skin cancers of the face, probably due to this cause. Then I know of two instances of lung cancers in husband and wife; one of a wide ulcerated abdominal wall sarcoma where the husband after months of helping with the dressings had a histologically similar spindle-celled sarcoma of the foot; a rectal case in which a young maidservant had apparently become infected from her mistress by using her enema syringe—confirming two similar instances noted by Bland-Sutton (from Macewen, *Tumours*, 1922 ed., p. 268); and there are probably more uterine cervix and penile cases than "chance" would account for (Leighton, 1932; Desaive, 1933). There are also the two striking instances, almost certainly infective, detailed in my book *Periodicity and Cause of Cancer* (1940, p. 109).

For contagion to be possible an abrasion on the skin or mucous membrane would seem necessary (as scratching, or rough use of an enema syringe), but given such an opportunity can *all* open cancers be considered 100% non-contagious? There may be only a decimal percentage involved, but is it scientific to ignore this possibility? In any case is it wise to draw rigid conclusions about a disease the cause of which is not yet known? Should cancer prove in the end to be a virus disease (see Oberling's recent *Riddle of Cancer*), open cases of cancer should be considered *possible* sources of infection, though to a much less degree than many other virus diseases, as warts.

John Knyveton's Diary

Prof. MILES PHILLIPS (Carmarthen) writes: I am interested in your reply to the question on the probable origin of the *Diary of a Surgeon in the Year 1751–1752.* I would venture to amplify it by quoting a note written by myself in December, 1941, on the fly-leaf of my own copy of this book: "I have no doubt that this *Diary* is an artefact, largely based on the *Memoir of my own Life, written in 1779,*" by Thomas Denman, M.D. (1733–1815), and on the *Continuation* of that *Memoir*, signed B, and written, no doubt, by his son-in-law, Matthew Baillie. Convincing evidence of this is to be found by comparing statements on pages, 4, 5, 6, 147, 313–16 of the *Diary* with statements on pages lix, lxviii–lxxii, and lxxvi–lxxviii of the *Memoir* and its *Continuation*, which are to be found in the seventh edition (London, 1832) of Thomas Denman's *Introduction to the Practice of Midwifery*. The mind of a reader of the *Diary* is somewhat prepared for the possibility, by a reference in the "editor's note," to "this being an age of impudent literar allusions."

Dr. J. F. BLACKETT (Bath) writes: I have made the followin additional criticisms of Knyveton's Diary (April 21, p. 579): the are, of course, of little importance except from the point of vie of establishing authenticity. "The Village of Hestley, Kent" (p. 9) is not mentioned in the gazetteers I have been able to consult In England, Sept. 2, 1752, was followed by Sept. 14, to adjus to the Gregorian Calendar; and the dates Sept. 3–13 inclusive o pages 270 to 283 had no existence. The change, however, may no have been observed by ships at sea. If Aug. 30 (p. 269) was Sunday, as it was, and the change to the Gregorian reckonin ignored, then Nov. 7 (p. 306) would be Saturday, not Sunday a stated—and so would Nov. 14 and 21 (pp. 307 and 309). In Englan they were Tuesdays.

Malaria and Syphilis

Brig. T. E. OSMOND (Ashford, Middlesex) writes: Whils being the last person to question your omniscience in most matters I cannot agree that "there is no evidence that malarial infectio has any therapeutic effect on a *Treponema pallidum* infection" (*B.M.J.*, April 28, p. 618). Surely the well-known effect of induce malaria on G.P.I. gives the lie to this. Your inquirer might b interested to read an article by A. A. Rosenburg (*J. Lab. clin. Med.* 1945, **30**, 149), who claims to be able to distinguish between positiv serum reactions due to syphilis and malaria respectively by precipitating syphilis reagin with ammonium sulphate.

⁂ Is not the emphasis on "infection"? And is not the successful treatment of G.P.I. by malaria due to its pyrogenic effect?—ED., *B.M.J.*

The Examiner's Attitude

Dr R. G. BLAIR (New Buckenham) writes: The letter from Mr. H. I. Deitch (March 31, p. 470) on the examiner's attitud prompts me to support the writer's views from a different angle For the past fifteen months it has been my lot to study specialists opinions in many hundreds of different cases. The gross difference of opinion expressed by specialists on many individual cases leav me with the impression that if either specialist were being examine by the other for a higher degree he would be ignominiously failed I have long felt that our system of examination as a qualifying process leaves much to be desired, and I would suggest that the furthe we get from purely clinical diagnosis, and the more we depend o mechanical aids to investigation, the greater will be the margin o our inexactitudes.

19th General Hospital

Col. JAMES O'GRADY writes from Stoneacre, Swinton, Manchester: Please allow me to bring to the notice of past and present member of 19th General Hospital the fact that an Old Comrades Associatio is in process of formation. I should be glad if any officers, nursing officers, warrant officers, or other ranks, who are interested, and ar or have been on the strength of the unit, would send me a postcard giving rank, name, and present address; I will then forward a form of application for membership.

Corrections

We must apologize to Dr. P. Ellinger for errors made in sending his letter "Detection of Nicotinic Acid Deficiency" (May 12, p. 678) to the press: 2nd paragraph, line 12, should have read, "Najjar in his latest paper *did not* propose . . ."; ante-penultimate line of 2nd paragraph, "Nicotinamide is *not* considered"; 3rd paragraph, 7th line from end, "nicotinamide" should have read "nicotinamide methochloride"; the last line but one of the 4th paragraph should have read "(20 to 50% of the values found in healthy people) were . . ."

Dr. R. CRUICKSHANK writes: May I correct some ambiguities in the report on my remarks at the R.S.M. on penicillin in urinary infections (*Journal*, May 12, p. 674). (1) The last sentence of paragraph 2 should read, "and therefore reliance must *not* be placed . . ." (2) In the table, the sensitivity of coliform organisms should be 15–30 units, not 30–60. The word "ratio" should be omitted. The point of this table was to show that with a daily dosage of 100,000 units of penicillin a urinary concentration of 30–40 units per c.cm. could be obtained, and therefore penicillin could be used in the treatment of urinary infections due to *Str. faecalis*, *B. proteus*, and some of the coliform organisms. In my concluding remarks I said I had recently visited a Canadian hospital in this country where they were using highly purified penicillin, and it was the custom there to use procaine as the patients objected if the local analgesic were omitted. Omission of the night doses could be done in the treatment of more localized infections, but not in septicaemic conditions.

Mr. HERBERT BROWN (Worthing) writes to correct two errors in his letter of May 5 (p. 645): (1) he entered U.C.H. in 1881, not 1880; and (2) was house-physician to Ringer in 1886, not 1881.

THE INTEGRATION OF MEDICINE*

BY

F. M. R. WALSHE, M.D., D.Sc., F.R.C.P.

In the course of discussions upon the future and development of medicine two themes recur with melancholy iteration—namely, that specialism is an evil, and that it is inevitable. For this dilemma in which it seems generally agreed that we find ourselves no one proposes a remedy, or lights the path we must follow if we are to discover one. In his Harveian Oration of 1931, before the Royal College of Physicians, Sir Robert Hutchison spoke with insight into our situation when he said, "Specialism is inevitable; but though favourable to the accumulation of facts, it is bad for the philosophy of knowledge. There is too little speculation and too little use of the imagination; and most scientific literature is barren in ideas." Therein he put his finger upon a malady of modern science.

Yet whether the remedy the Harveian orator proposed is one we can adopt is open to question, for he went on to say that "it might be a good thing if there were a close time in laboratory work, say for five years, to enable us to digest the vast accumulation of knowledge we already possess and to think out new lines of advance." Yet I doubt if in the present climate of opinion, five years of research inactivity would increase interest in the use of the intellect, while, on the other hand, if we could stimulate this interest, a five-year truce with facts would be neither necessary nor desirable. The average modern scientific worker, paradoxical as the suggestion may seem, is more apt to be a man of action than of thought. He tends to distrust ideas. He has not always learned to achieve a harmony of observation and of general thought. His output of facts is necessarily reduced if he pauses to think about them. It may then easily be said of him that he is not making "discoveries" as fast as he should. In any case we cannot dam the stream of research effort, even if we do see too much of it losing itself in the sands.

It is significant that it is in medicine, and not in its so-called ancillary sciences where the situation is not essentially different, that an acute consciousness of the dilemma I am considering should first have dawned. Reasons for this are easily found. Let us take the case of physiology as example. This is now busily exploiting the harvest of technological advances in all fields of science, and is adapting to the solution of its own problems the methods which these sciences—physics, chemistry, and biochemistry—are so richly providing.

It has thus come about that a given physiological problem, such as the nature of cerebral cortical function, may now be approached from so many angles that it assumes the appearances of, and is too readily taken to be, many disparate and unrelated problems. All effective communication in thought ends to be broken between the users of the different exploraory techniques, and information accumulates while generalization wilts and dies. To use an expression familiar to readers of war reports, the physiologists are "fanning out" into the unknown, and in this active stage of their advance fail adequately to realize that co-ordination of thought and aim must be retained if physiology is to be a coherent body of knowledge. Let me take again, as an example, the problem of localization of function in the cerebral cortex. Over fifty years ago Hughlings Jackson, the clinician who discovered the *fact* of localization of function within the cortex, being a man of ideas, also made some penetrating generalizations as to the *nature* of this localization. The era of experimental study of this problem opened very shortly afterwards, and has since been pursued with ingenuity, with eagerness, and by an increasing number and variety of techniques—the most modern ones being of great refinement and delicacy. Yet there has been no comparable development of thought upon the subject, and a crude notion that sees in the cerebral cortex a mosaic of sharply delimited localizations of fragments of function has survived virtually unaltered since the pioneer experimental investigators first bent their energies to the task of discovery. During all this time Jackson's interpretation and synthesis of the facts have scarcely influenced thought. It is not that this interpretation has failed to generalize the facts, it is simply that it has largely failed to excite the interest of research workers. The taint of ideas that clung to it, and the bend sinister of its clinical pedigree, have together provided the experimentalist with an excuse not to think about it.

Nor is this preoccupation with the collection of information the only factor in the disorderly state of knowledge on this and allied subjects. As Trotter has pointed out, and abundantly exemplified, in more than one of his penetrating addresses, physiologists commonly, and naturally enough, pursue their science for its own sake. Theirs is therefore by definition a liberal profession, while that of a physician is a useful one. I make this distinction in no invidious sense, but in the sense employed by Newman in his lectures on "The Scope and Nature of University Education," where he says, "That alone is liberal knowledge which stands on its own pretensions, which is independent of sequel, expects no complement, refuses to be informed (as it is called) by any end, or absorbed into any art in order duly to present itself to our contemplation." This quality, which physiology as a branch of liberal knowledge shares with such physical pursuits as cricket and fox-hunting—as Newman also points out—is not shared by medicine, whose activities have an end other than themselves: namely, the health and well-being of the community.

I do not wish to be taken as implying that the fruits of physiological research are not useful—indeed, we know that they are not rarely potent weapons in our hands—but as emphasizing that this last result is, when it happens, fortuitous, and is not one that the physiologist as such intends or is interested in. In short, in medicine we have to apply our knowledge, however garnered, to well-defined ends, to the prevention and cure of illness and, as a corollary to this, to the training of the doctors of the future. It is this that brings home to us, whether we will or not, the dangers inherent in the unceasing expansion and differentiation of the field of knowledge. As has been aptly said, once we seek to go beyond the basic elements of medicine as we know it, we tend to know more and more of less and less. Thus it happens that those responsible for the training of our successors too often find themselves imparting unrelated categories of information and partial and often conflicting generalizations culled from different fields of medicine, and it is becoming nobody's business, and seems less and less within anyone's capacity, to teach medicine as a whole, or to build into a coherent body of knowledge the several contributions of the specialists.

---

* Being an abridgment of the Annual Oration of the Medical ociety of London, May, 1945.

It is therefore because ours is a useful rather than a liberal profession that we have been forced to face the situation created by the accumulation around us of more, and more diverse, information than we can digest and assimilate. Hughlings Jackson was clearly aware of this, over 50 years ago, when he said that "we have multitudes of facts, but we require, as they accumulate, organizations of them into higher knowledge; we require generalizations and working hypotheses. The man who puts two old facts into new and more realistic order deserves praise as certainly as does the man who discovers a new one. There is an originality of method." But in this, as in much else, Jackson was before his own time and ours; and thus it is that physiology, true to its nature as a branch of liberal knowledge, sees no reason why it should not continue to browse at will upon the rich pastures of uncropped knowledge, giving no thought to any philosophy of knowledge, while medicine, faced by its ultimate purpose, has clamant responsibilities in the ordering of the knowledge at her disposal, and in the maintenance of a balance of activity and thought, that she dare not continue to evade. Medicine, then, has come to see that the unending additions to knowledge call urgently for a corresponding measure of integration. Yet we must try to strike a fair balance in this matter. Let it not be thought that I am making odious comparisons between physiologist and physician. We are both in the same boat, and in medicine we need not flatter ourselves that it is primarily out of any intellectual disquiet, or out of a divine discontent with the chaos of information that lies around us, that we have been brought to realize our dilemma—namely, the necessity and the evil of specialization. We are as innocent of any philosophy of knowledge as the physiologist. Our concern arises because much that is implied in the term "specialism" has come to be an obstacle to the teaching and practice of medicine.

Nevertheless, by whatever channel this awareness of the disorderly state of our science has reached us, we are at least generally agreed that we cannot indefinitely go on as we are, and that something must be done to bind the broken foundations of medicine and to make it something more than a congeries of ingenious techniques and unrelated fragments of knowledge. This, at any rate, however gained, is something gained.

Integration Keeps Pace with Differentiation

The thought that I am trying to develop will be familiar to many of you. It is summed up in the aphorism so familiar to neurophysiologists, "Integration keeps pace with differentiation." This is a fundamental principle in the evolution of the nervous system, and I cite it because I believe it to have a vital meaning for us in my present connexion. We owe its original formulation to the now disregarded genius of Herbert Spencer, from whom it was taken, and so fruitfully employed, by Hughlings Jackson. Derived anew from this latter source, it became a guiding inspiration in Sherrington's monumental contributions to experimental physiology, and its influence may be seen in the title he gave to his classic work of 1906, *The Integrative Action of the Nervous System.* Yet it is not so much with integrative action of the nervous system in respect of the organism as a whole that I am now concerned as with the development within that system, as it becomes progressively more differentiated, of structures and functions designed to control and to unify the several parts and to make them into a harmonious whole. In short, integration does, as an observed fact, keep pace with differentiation in the evolution of that system.

This conception is capable of a wider meaning than that given to it by the physiologist. I submit that it expresses something inherent in scientific thought and constantly found in truly scientific endeavour.

Let us now replace the term "differentiation" by "observation" and the term "integration" by "interpretation and synthesis." Observation leads to the increase and differentiation of information, while interpretation and synthesis are its integration into ordered knowledge, and I suggest that in the process of scientific thinking interpretation and synthesis must keep pace with observation if a coherent body of knowledge is to be forged. From this we pass easily and naturally to the notion that there is a rhythm in scientific thought, the two elements observation and interpretation alternating.

The feeling that there is such a natural rhythm in thought, a cycle in which observation and interpretation alternate, is widely implicit in our literature in respect of all branches of knowledge. It finds expression in such a statement as that of Lord Acton, "The main thing to learn is not the art of accumulating material, but the sublimer art of investigating it." While in Matthew Arnold's essay on *The Function of Criticism* we read, "The grand work of literary genius is a work of synthesis and exposition, not of analysis and discovery." Coming to our own field, we find Abraham Flexner writing: "Data of one kind or another are not so difficult to obtain; but generalization is another matter. . . . The two processes—the making of hypotheses and the gathering of data—must go on together, reacting upon each other." But the notion gets its fullest and most explicit formulation in a passage from the first volume of Arnold Toynbee's *Study of History*, which I have already quoted elsewhere, and do so again, to reinforce the cogency of my theme with the authority of this erudite thinker on history. He says:

> "Scholarship makes its progress by a rhythmic alternation between the two activities—the collection of materials and their arrangement, the finding of facts and their interpretation—just as a physical organism lives and grows by an alternation between eating and digestion. The old fable of the belly and the members points the moral that neither activity is superior or inferior, prior or posterior, primary or parasitic, but that each is inseparable from the other as a part of the same whole, and complementary to the other as a phase in the same recurrent process. For the alternation perpetually recurs in virtue of the very nature of thought. When the mind is employed in finding facts, its sheer success inhibits it sooner or later from fact-finding uninterruptedly and *ad infinitum*. Sooner or later it finds itself so formidably beleaguered by the mass of facts which it has gathered round it that, until it has sorted them out and arranged them in some kind of order, it can no longer sally out into the Universe to gather more. Then the mind changes its activity perforce and employs itself for a season in making syntheses and interpretations. Yet now, once again, its sheer success inhibits it from working uninterruptedly and *ad infinitum* at bringing order out of chaos. Sooner or later, it finds that it has reduced to order all those materials which it had collected in its last fact-finding reconnaissance. Fresh facts must now be found before the process of synthesis and interpretation can be carried further. . . . No collection of facts is ever complete, and no synthesis or interpretation ever final. . . . This rhythm is native to thought in all its different channels. In the channel of Physical Science, we have seen that thought has recently passed out of a fact-finding phase into the next phase of synthesis and interpretation."

Thus Toynbee, and, *mutatis mutandis*, what he has to say of the study of history applies to medicine and the sciences ancillary thereto. In a remarkable foreword to his book on anaphylaxis and immunity, Maurice Arthus, with a true French fire and clarity, tells us how this balance is to be achieved; and how vital to science it is. This foreword has recently been translated into English under the title of *The Philosophy of Scientific Investigation* by Sigerist, and published by the Johns Hopkins Press. He says:

> "The experimentalist must ponder and meditate deeply over the problems raised. . . . In order to make some progress in the experimental sciences one must meditate a great deal. I have repeatedly mentioned," he goes on, "the necessity of controlling the facts observed, of discussing the interpretations proposed and the meaning attributed to them, in order to accept as true and valid only what has stood the indispensable test of scientific criticism. This presupposes a special mental attitude which, unfortunately, is hardly developed in the schools, colleges, or perhaps even in the universities—namely, critical sense. This is the tendency of the mind to seek the true value of facts and results, of methods and of concepts."

It should not be necessary for me to labour this point any more, yet I believe that few would contend that during our time either medicine or its ancillary sciences have consistently honoured these principles of scientific thought, or have conformed to this rhythm of which Toynbee speaks as "native to thought in all its different channels." We have in fact, with some brilliant exceptions, been far too readily satisfied with fact-finding, and too little regardful of those intellectual instruments by which facts are interpreted and generalized. The work of Hughlings Jackson was such an exception, and another that stands out in my mind is that of Sherrington in the field of physiology. I can yet recall the feeling of exaltation with which, as a student of physiology over thirty years ago, I first read his *Integrative Action.* Here were new facts of observation in rich abundance, and how beautifully coordinated! With what logical precision the exposition of them advanced from step to step, and with what penetrating scientific imagination was their significance revealed! This perfect rhythm of observation, interpretation, and synthesis, which is the hall-mark of scientific genius, has characterized all Sherrington's work and has made of it a unified whole, a brilliant chapter in the story of the nervous system.

In the clinical field we see the same brilliant qualities informing the studies of Trotter and Davies on cutaneous sensibility. Here, within the brief scope of two papers, we find as complete a harmony of observation and interpretation and as finished a piece of medical research as modern medicine has to show. A comparable trend is seen in Head's work on sensation, a rhythm of observation and interpretation and a continuity of thought over a long-sustained research; and if the observations in some details have since proved fallacious and the interpretation sometimes unduly abstract, the whole is an impressive example of the normal rhythm of scientific thought with its own elements of grandeur.

To sum up this stage of my thesis, therefore, we see that as new facts increase in number and diversity, the need for their interpretation and synthesis increases in corresponding degree. By these means we forge those general principles that keep knowledge coherent, and make of it truly scientific knowledge.

One is sometimes asked what, precisely, one refers to by principles of medicine, and I admit that the term is apt to be used without due definition. Let me tax your patience by yet another example from the field of neurology. The generalizing mind of Hughlings Jackson, surveying the wide range of phenomena of disease of the nervous system, discerned that the totality of these phenomena could be subsumed under four headings, that the functions of the nervous system could react to damage in but four essentially different ways, whatever the aetiology of the pathological process concerned. He thus was able to formulate four corresponding generalizations. He then went further, and, taking the phenomena of nervous disease as a whole, he saw that these constituted an orderly reversal of the natural evolution of function in the nervous system, whether considered phylogenetically or ontogenetically. He was thereupon able to formulate a further and wider generalization—namely, a general principle of dissolution of function in the nervous system. Although seventy years have elapsed since this was expounded—years rich in new knowledge of relevance to the problem—it still provides a generalization of wide validity and great usefulness. Thus, however discouraging the therapist may find diseases of the nervous system, we have in neurology a coherent body of knowledge more closely based upon anatomy and physiology than any other branch of medicine, saving only cardiology, which has a body of general principles of a like order. Such a consummation should be our aim over the whole field of medicine.

No one will deny that there are dangers inherent in the use of generalizations—for example, the tendency to fit the new facts into the procrustean bed of theory, where knowledge may become rigid and die. Abstract thinking has indeed been described as "a major vice of the intellect," and no one has spoken more cogently of its dangers than Trotter. Nevertheless, he has also told us that ideas keep science fresh and living, and when properly used are in no danger of ceasing to become the nimble servants of truth. Therefore, even though the intellectual instruments of abstract thought and generalization may turn in our hands, we must yet use them if we are to advance.

Now, those of you who may be ready to accept the point of view I am trying to advance may still ask me how we are to apply it. How are we to reduce the vast accumulation of facts to some sort of order, to elicit general principles, and to build a coherent science and art of medicine? From the very nature of things we shall never achieve finality, but at least we can try to tidy up as we go along.

I believe, in brief, that we must be imbued with a vivid realization of the fact that scientific thought and activity make up a rhythm of which observation on the one hand, and synthesis and interpretation on the other, are the elements, and that the mere eliciting and recording of factual details is by itself not science, and does not become so until the cycle is complete. In other words, we need a wholesome respect for ideas as an integral part of scientific thought. I cannot help thinking that if in every centre of original work, clinical and laboratory, workers were constantly aware of the principle that integration of knowledge should keep pace with its differentiation, we should find many fewer disjointed and apparently purposeless observations swelling the monstrous bulk of scientific literature. I sometimes doubt whether one is justified in recording in print a new observation unless one also seeks to indicate what it holds, and to apply the inductive process to it. One should not fling a raw fact on to paper in public, as a keeper flings a chunk of raw meat to a tiger. I believe that in medicine we have a unique advantage in this respect over the purely experimental scientist, in that medicine, while becoming increasingly an experimental, has long been and must continue largely to be an observational science. In its observational aspect it deals with a supremely difficult material under conditions that make constant demands upon intuition and judgment. Nature is not interested in scientific method, and the experiments she provides for us in the guise of disease and injury we have to take as we find them; we cannot subject them to the necessary but artificial simplification that is the essence of a good experiment. We are therefore forced to think, to synthesize, and to interpret our evidence to a point rarely necessary in the designed laboratory experiment. While, therefore, we must welcome the increasing role of experiment in the study of medicine, we must be on our guard not to be infected by the distrust of ideas characteristic of much experimental work, but continue to use the intellectual assets which experience of clinical observation gives every good doctor.

I confess that I have inflicted many quotations upon you, a fault which one filling the role of orator should never commit, but my object in doing so is to emphasize, as clearly as I am able, that my thesis is no new one, no private bee buzzing in my bonnet, but one that has often been maintained and exemplified by those whose labours in the realms of observation and ideas have shone most brightly before us.

Tasks Involved in Rebuilding of Medicine

If you have followed me so far, you will probably agree that there is one simple way in which each of us can contribute to the integration of medicine—by seeing that in any addition we may be able to make to the sum of medical knowledge we tidy up as we go along and conform to the natural rhythm of scientific thought, and that we try to build our fragmentary contribution into the general body of relevant knowledge.

A second task involved in the rebuilding of medicine is to ensure, as and when the human resources are available, that those who hold key positions in centres of medical education and research shall be men interested not only in research and routine teaching but also in general ideas.

This may prove no easy task, for such men are rare, and the trend of values hitherto has not been such as to encourage them to follow their bent. You cannot find them by offering professorships, as some suppose, but you can always offer them full opportunities when you find the men. Encouragement must begin when they are young, and before they become moulded or resigned to the ephemeral patterns of current orthodoxy. The young worker must be allowed to retain his intellectual independence and to pursue the problems he has found for himself—as the best men do find them for themselves; he must also be allowed some vestige of freedom by the editors of those scientific journals in which his work reaches the world, in developing his ideas, so that his papers are not reduced by the editorial blue pencil to those drab sequences of experimental protocols that for too many appear the ideal of a scientific paper. An editor should be "no envious Juno sitting cross-legged over the nativity of any man's intellectual offspring," as Milton says; and whoever believes that the censorship of ideas survives to-day only in the totalitarian State imagines a vain thing. The original sanctions may have gone and a censorship's formal existence have ceased, but the itch to suffocate the infant idea burns in us all in greater or less measure.

I may seem to have wandered far from my opening theme —namely, the evil and the necessity of specialism in medicine —but I believe that in fact I have not done so. The danger of specialism is not so much that a man devotes his major activity to a restricted field of knowledge in medicine, but that he is so apt to become absorbed in its details, and still more in those of the complex instruments that are now so freely at his disposal, that he unwittingly cuts adrift from the general body of medicine and goes off on a voyage of his own.

There are in truth no irrelevances and no contradictions in nature, nor can there be in any coherent body of knowledge. The specialist, therefore—and I use the term in its strict and not in its journalistic sense—must cling fast to the foundations of medicine, for only thus can he integrate his contributions to knowledge and orient them, and avoid the multiplication of those conflicting *ad hoc* hypotheses with which medical and allied literature are littered.

So, too, the teacher of medicine has a like obligation to interpret so far as possible and to keep a lively interest in general ideas. This applies with greater force to the academic than to the purely clinical teacher, who has a major responsibility in handing on the art and the techniques of medicine.

Last, there are our textbooks. It has now become the almost universal practice for a textbook of medicine to be the algebraical sum, if not often the integration, of the knowledge of a body of specialists. There is a danger inherent in this plan, forced upon us though it may be, for it demands in the editor of such a compilation gifts of detailed knowledge and of generalization that few can hope to possess. In these circumstances, also, an editor has to have a clear idea as to the circle of readers he is providing for, as to the particular want he desires to satisfy. What is best for the student is not necessarily adequate for the follower of higher studies, and what the latter requires is not the diet for the student. Too often we see an attempt made to make the best of both worlds, with the result that neither is wisely catered for. Of all textbooks it may not unfairly be said in our day that they are more interested in facts than in ideas, and an urgent task before us is some recasting of them. It is significant of the trend of current thought that whereas formerly textbooks of medicine claimed to expound the "principles and practice" of medicine, no modern work of the kind makes even a titular claim to concern itself with principles.

Finally, there is a pseudo-integration of medicine against which we are not always sufficiently on our guard. This is exemplified in the numerous doctrines of those who see their own specialty everywhere in medicine, who have their own touchstone by which all the phenomena of illness are to be assessed. They measure every man's corn by their own bushel, and are obsessed by this or that cult of ideas and are always proselytizing. They make up those cohorts of hobby-horse riders who cavort noisily to and fro across the field of medicine, throwing up little but dust into our eyes.

The Role of General Education

Now if this notion of what is requisite to advance in medicine has validity it must presuppose an adequate general education as a foundation. If those who come after us are to be equipped to observe and describe accurately and interpret logically and imaginatively, their training to these ends must begin while they are still young, and their school education should not be based upon short-sighted utilitarian considerations, or be of what I may call a polytechnic order, but should include as its very foundation a thorough training in the use of that noble instrument for the expression of thought and feeling, our mother tongue, in the expansion of that instrument by the right use of analogy, and in its logical employment.

In brief, what I am invoking are the three arts of grammar, rhetoric, and logic. If we lack a command of language we cannot hope to produce, formulate, or entertain general ideas or make even the simplest essays in abstract thinking.

Now, those who are familiar with the aims and methods of the mediaeval university will recall that these three arts, composing what was called the trivium, formed the basis of university education. It may perhaps be argued that in the Middle Ages, the ages of scholastic philosophy and of theological disputation, these three arts tended to be followed as an end in themselves, that the training in clear exposition and thought was what I have already called a liberal education with no end other than itself, and that it led to mere logic-chopping and to no advance in natural knowledge. Some of this may be true; I express no view upon it, and I am not proposing the revival of these arts merely as an entertaining and stimulating variety of mental gymnastics. I put them before you as an essential preliminary to that clarity of thought and expression that is one of the weapons of scientific advance, of the tools with which we pursue natural knowledge. From which it follows that the greater our command of language, the more clearly and deeply we can think and express our ideas. I submit, therefore, that a command of language, and its logical use, are vital preliminaries to any scientific training.

Some may ask me where rhetoric comes in. In its original and its mediaeval sense it refers to the expansion and condensation of discourse by analogy and figure of speech. Wherever we find lucid and vital English, there we find rhetoric. What a text of lovely and illuminating rhetoric are the psalms, for example. Rhetoric has its place in the expression of those ideas we derive from the study of facts, nor can we teach without it.

In short, what I am proposing is that a humane education is an invaluable asset to any youth embarking upon the study of medicine. I am aware that I raise the banner of a forsaken cause when I say this; but nevertheless, twenty-five years of clinical teaching have fully persuaded me that when I find a clinical clerk who can stand up and read at a ward visit a case history that is a well-ordered, lucid, and fluently expressed account of the patient and his situation, that student will almost invariably be found to have had a sound education, and not a mere course of instruction of the polytechnic order, a utility education. This is why we must all deplore the practice of turning boys over to premedical subjects exclusively, or almost exclusively, directly they jump the hurdle of the school certificate. Too often they come to us semi-articulate, their budding ideas imprisoned behind the bars of an inadequate command of expression. It is between the ages of 14 and 18 that the capacity for pursuing a line of thought and for abstract thinking develops, and it is then that the adolescent should find himself provided with the necessary instruments of speech. "Give me," says Milton, "the liberty to know, to utter, and to argue freely." If we changed this by saying "Give me the literacy to know, to utter, and to argue freely" we should not really be altering the sense, for it is the capacity to express it that gives liberty to thought.

Conclusion

What I have had to say is somewhat remote from the medicine that presents itself to us in our daily lives. Yet as we grow older the urge to lift our eyes from the details of the little plot in which each of us labours becomes ever stronger, and we are impelled to look round upon the wider field of natural knowledge as a whole. Some may even feel the pull towards some philosophy of knowledge, towards those common truths to which all science must be obedient. Man does not live by facts alone, but craves also for generalizations, and the desire for some philosophy of knowledge burns, if with varying intensity, in all of us.

Looked at in this spirit, how untidy and in places how overgrown the field of medicine seems to be; in other places how bare, how precariously balanced the whole upon the uncertain foundations of biological knowledge! So it must remain until we develop a wider and deeper consciousness of what constitutes ordered knowledge, and by what cycle of thought it is to be achieved.

Yet to feel some discontent with medicine as we find it does not imply any lack of pride in its achievements, nor any diminished sense of privilege in seeking to serve it. If one is a critic, it is, I trust, in the spirit expressed by Milton when he says, "For he who freely magnifies what hath been nobly done, and fears not to declare as freely what might be done better, gives ye the best covenant of his fidelity."

ON THE DIFFERENCE BETWEEN THE SEXES IN DISPERSION OF INTELLIGENCE

BY

J. A. FRASER ROBERTS, M.D., D.Sc., M.R.C.P., F.R.S.Ed.

Temp. Surg. Cmdr., R.N.V.R.; Consultant in Medical Statistics, Royal Navy; Director, Burden Mental Research Department, Stoke Park Colony, Bristol

It is a striking fact, though it is in no way surprising, that in mean performance on intelligence-test scales there should be no difference between boys and girls. On the other hand, and especially in view of this first result, it is one of the oddest facts in the whole field of human biology that boys should be more variable than girls. Furthermore, as will be shown, the difference is not merely a small one, considerable though the academic interest of this would be; it is a large difference with important practical implications. Gifted boys are more numerous than gifted girls, the discrepancy increasing as we pass further away from the average performance of the whole population; till, actually, the performance of the cleverest boy in each 1,000 boys is equalled by only one girl in each 2,000 girls; thus at this level highly intelligent boys are twice as numerous as girls. All this is, however, exactly counterbalanced at the other end of the scale, dull boys being more numerous than dull girls and very dull boys correspondingly much more numerous. In other words, girls tend to be grouped closer to the average for the whole population, while boys tend to spread further over into extremes of brightness or dullness. In the planning, therefore, of such things as the provision of facilities for higher education, a greater percentage allotment should be made for boys than for girls. Similarly, greater provision for boys is needed in special classes and schools for the backward and, to the extent that mental deficiency depends upon intellectual retardation, much more in institutions for mental defectives.

Existence of the Difference

The sex difference in dispersion of intelligence is an empirical observation: so far as I know, nothing analogous has been demonstrated, and it is difficult to think of any convincing biological explanation. In these circumstances it has been naturally and rightly felt that strong evidence should be forthcoming before so curious a finding should be accepted.

From the early days of accurate mental measurement indications of the difference began to appear, though by no means invariably in all studies. It is easy to see why results should have been conflicting. In the first place, relatively large numbers are required in order to detect a difference in variability—considerably larger than those required in order to detect a difference in means; from this point of view most samples were very small. In the second place—and this is much more important—it is very difficult to secure a random sample of intelligence-test results. Bias in the sampling of school-children tends especially to affect the extremes; hence the sex difference in dispersion is particularly liable to be artificially minimized. For example, my colleagues and I (Roberts, Norman, and Griffiths, 1935) have shown that the omission of private-school children from a complete group considerably diminished the difference. For these reasons, Winsor, writing as late as 1927, could still conclude, after a careful review of the literature, that the evidence was insufficient.

Not until the appearance of that magnificent piece of work, the survey carried out by the Scottish Council for Research in Education (1933), was all legitimate doubt at an end. In this survey both the difficulties mentioned above were admirably countered. The numbers tested were vast, being no fewer than 87,000; and every effort was made to secure completeness of sampling, the aim being to test a complete annual age group throughout the whole country. It is true that some unavoidable bias remained, but in excellence of sampling no less than in numbers this group was a great improvement on its predecessors.

A good verbal group-test was applied, the results being as follows:[*]

Difference in Mean Performance between Boys and Girls

	No.	Mean Score
Boys	44,210	34·506
Girls	43,288	34·411

Difference = 0·095±0·105

The difference is less than its standard error, so that, even using such large numbers as these, it is impossible to decide whether boys or girls have the higher average performance.

The variances tell a very different story:

Difference in Variance between Boys and Girls

	No.	Variance
Boys	44,210	253·747
Girls	43,288	225·605

Difference = 28·142 ± 1·885

This very large difference is no less than 14.9 times its standard error.

The existence of the difference is abundantly demonstrated, but two important points must be considered: it is demonstrated using this particular test and for this particular sample; is there any reason to anticipate that using another scale or another sample the same result might not be obtained?

First, as regards the test, good scales designed to measure general intelligence correlate so highly with each other that it is, to say the least, extremely unlikely that the sex difference would not appear whichever was used. Direct proof, however, is not lacking. The Scottish investigators retested a sub-sample of 1,000, using the Stanford-Binet scale. A certain lack of randomness in the sampling complicates interpretation, but it was shown that the difference is clearly apparent on the Binet scale also.

My colleagues and I used a different verbal group-test, the advanced Otis, in our survey of school-children at Bath, as described in a series of papers (Roberts *et al.*, 1935, 1937, 1938a, 1938b; Roberts, 1940). Our results are as follows:

Difference in Mean Performance between Boys and Girls

	No.	Mean
Boys	1,742	100·743
Girls	1,606	99·790

Difference = 0·953 ± 1·187

Difference in Variance between Boys and Girls

	No.	Variance
Boys	1,742	1296·38
Girls	1,606	1066·26

Difference = 230·12 ± 53·75

Just as in the Scottish survey, there is no significant difference in mean performance but a very large difference in variability, this being 4.3 times its standard error.

As regards the sampling, it has already been mentioned that the Scottish group was carefully selected; such bias as there was could not affect the magnitude of the difference materially, and in any event would tend to diminish and not to increase it. The Bath group is, of course, much smaller, but even greater care was taken to ensure completeness. The aim was to ascertain and test every child whose time of birth fell between certain dates, and whose home was within the boundaries of the city on a given date. As described in the papers quoted, this aim was very nearly attained.

It can be safely concluded, therefore, that any good test of general intelligence applied to any good sample will show the difference in dispersion between the sexes; boys and girls do not differ in mean performance, but boys are quite certainly more variable.

---

[*] All calculations in this paper on the Scottish survey results are based on the tables given on pages 61 and 62.

Size of the Difference

The reality of the difference between the sexes has been demonstrated, but the available information permits us to take the further step of making a useful estimate of its magnitude. How much more variable are boys than girls? The ratio of the variances in the Scottish survey is (using Sheppard's adjustment for grouping) 245.414/217.272 = 1.130. Boys are therefore 13% more variable than girls.

The numbers included are large enough to provide a high degree of accuracy of estimation. The odds are 1 in 20 that the true value lies outside the range 11.2 to 14.7%; they are 1 in 100 that the true value lies outside the range 10.7 to 15.2%. These limits are, however, once again subject to the provisos: on this test and in this sample.

In the Bath experiment the ratio of the variances is 1294.30/1064.18 = 1.216. Boys are thus 21.6% more variable than girls; but as the numbers are smaller than those of the Scottish survey the limits of error are much wider. The odds are 1 in 20 that the true value lies outside the range 11.7 to 31.5%, and 1 in 100 that it lies outside the range 8.6 to 34.6%. The results of the two surveys do not conflict significantly.

There are several factors which point to the conclusion that the Scottish figure is somewhat too low.

1. *Errors of Measurement.*—Verbal intelligence tests have relatively high reliability, and it is unlikely that the elimination from the variances of that part which is due to errors of measurement would raise the figure from 13% to more than about 14.5; nevertheless, such effect as there is must have lowered the difference between the sexes.

2. *The Composition of the Sample.*—Sampling was not quite complete, and a relatively small loss at the extremes would lower the difference appreciably. The Bath survey, in which the sampling was practically complete, does in fact indicate a higher value.

3. *The Nature of the Test.*—Good tests of general intelligence measure something which shows a wider dispersion among boys than among girls. It could reasonably be anticipated that different scales, highly though they all intercorrelate, vary somewhat in their efficiency in measuring that something; it is also to be expected that they contain in varying degree extraneous elements displaying no difference between the sexes. To say more would be pure speculation, but it can fairly be concluded that any given test will be imperfect, and to the extent that this is so the sex difference will be reduced.

Reviewing the available evidence, one might make two estimates of the amount by which the variability of boys exceeds that of girls. The most likely figure is perhaps about 17%. Because of the important practical consequences that follow, however, it seems preferable to select a conservative value—one which we can feel is almost certainly not too high. In view of the factors which must have tended to lower the ratio found in the Scottish survey, the figure of 13% would seem to provide this safe minimum.

Consequences of the Difference

The estimation of the difference has been considered in some detail. It is an important figure because we are unlikely to obtain a better one for a good many years to come. The dislocation of populations in most countries will make the task of sampling too difficult; and even in the United States it will be a long time, in all probability, before investigators can turn their attention to a new survey on an adequate scale. As we have seen, the figure of 13% for the greater variability of boys is conservative; it is extremely unlikely to be too high, though it may well be somewhat too low.

Accepting this figure, we can calculate the ratio of boys to girls in different portions of the range of intelligence. In the middle of the distribution—among, say, the 80% of persons nearest to the mean of the whole population—the disproportion is relatively small; but outside these limits it becomes considerable, and increases as more extreme fractions are considered. Thus the brightest 10% of boys are matched by 8.65% of girls; similarly for the dullest 10%. The brightest (or dullest) 5% are matched by just over 4% of girls. Beyond the level which cuts off the brightest (or dullest) 1% of boys there are three boys for every two girls. Beyond the extreme limit which cut off at each end of the scale one boy in every 1,000 boys, boys are twice as numerous as girls. Table I shows the percentage (or number per 10,000) of girls who correspond in intelligence to the brightest or dullest 10%, 9%, etc., of boys.

TABLE I

Cleverest (or Dullest) Boys per 10,000 Boys	Number of Girls of Corresponding Mentality per 10,000 Girls	Boys per 100 Girls
1,000	865	116
900	770	117
800	676	118
700	583	120
600	492	122
500	402	124
400	314	127
300	228	132
250	186	134
200	145	138
150	105	143
100	67	149
70	45	156
50	31	161
30	17·4	172
20	11·1	180
10	5·1	196

The comparison can be made in a different way. In a population composed of equal numbers of each sex how many boys and how many girls will be included in the brightest or dullest 10%, 9%, etc., of children of both sexes? These comparisons are given in Table II.

TABLE II

Cleverest (or Dullest) Children (%)	Numbers included per 10,000 (5,000 of Each Sex)		Boys per 100 Girls
	Boys	Girls	
10·0	534	466	115
9·0	483	417	116
8·0	432	368	117
7·0	380	320	119
6·0	328	272	121
5·0	276	224	123
4·0	223	177	126
3·0	169	131	129
2·5	142	108	132
2·0	115	85	135
1·5	87	63	138
1·0	59	41	144
0·7	42·2	27·8	152
0·5	30·6	19·4	158
0·3	18·8	11·2	168
0·2	12·7	7·3	174
0·1	6·5	3·5	186

What will sometimes be of interest is not the relative proportions among all those lying beyond a given limit, but among some section of that group. For example, one might wish to know the proportions of boys and girls in that portion of th range lying between the 90th and 95th percentiles—i.e., th children who are brighter than 90% of the population and duller than 5%. Any such figures can be obtained by difference from Table I or II. Thus from Table II the 500 childre out of each 10,000 who lie between the 90th and 95th percentiles will be composed of (534–276) = 258 boys and (466–224) = 242 girls—a proportion of 107 boys to 100 girls. Table III shows some examples for successive portions of the range.

TABLE III

Successive Portions of Brightest (or Dullest) 10%	Number per 10,000 (5,000 of Each Sex)		Boys per 100 Girls
Percentiles	Boys	Girls	
90–95 or 10–5 ..	258	242	107
95–98 „ 5–2 ..	161	139	116
98–99 „ 2–1 ..	56	44	127
99–99·5 „ 1–0·5 ..	28·5	21·5	133
99·5–99·8 „ 0·5–0·2 ..	17·9	12·1	148
99·8–99·9 „ 0·2–0·1 ..	6·2	3·8	163
99·9+ „ 0·1– ..	6·5	3·5	186

Space does not permit the provision of graphs from whic could be read off the proportions in any part of the rang It is hoped, however, that Tables I and II give enough deta to provide immediate answers to most practical questions

Proportions deduced on the assumption of equal numbers of boys and girls, as in Table II, will be only slightly in error if applied to populations showing the sex ratios commonly encountered.

The consequences of the sex difference in regard to such practical matters as the planning of accommodation are evident. If, for example, it were decided that a particular kind of secondary education was to be provided for the brightest 10% of children, the allocation should be for 10.7% of boys and .3% girls. If facilities for a particular type of higher education were to be offered to the cleverest 5%, this should comprise 5.5% of boys and 4.5% of girls; if the figure for another purpose were 2%, the allocations should be 2.3 and 1.7. If university scholarships of some special kind were available for 1% of the population, we should expect, if performance were proportional to mental endowment, to find a ratio of boys to 2 girls among the successful candidates. If, following Galton, we term the one person in a thousand of surpassing intelligence a "genius," we can expect to find that at this level men are nearly twice as numerous as women.

It should be stated, however, that while there is some risk of allocating to girls too high a proportion of special educational facilities, there is no risk at all, certainly not for many years to come, that opportunities for adult achievement will be vailable for women on too generous a scale. It will be ufficient to quote Terman (1940). More than 20 years ago he nitiated the researches embodied in successive volumes of *enetic Studies of Genius*. An attempt was made to include he most gifted Californian children of their time; the sample f some 1,400 corresponded to about one-half of 1%. A ollow-up after 16 years was designed to discover what use ad been made of these outstanding gifts. So little chance on he average had the girls had, however, that Terman was forced o confine his analysis to the boys. It would probably be true o say that the greatest reservoir of unused high intelligence our community is to be found in its female population, and hat this loss is not exceeded by that due to any other cause, ot even excepting social and economic handicaps.

At the other end of the scale, the dullest section of the opulation, matters are somewhat more complicated. The first omplication is due to the occurrence of idiots and imbeciles. These are not to be regarded as part of the normal distribution f intelligence; they are the pathological dwarfs of mental ature, and have been excluded from the calculations of this aper. Their frequency is about 4 per 1,000 among children school age. The figures in the tables therefore include only hose mental defectives who correspond more or less to the eeble-minded group. To these figures must be added the 40 r 10,000 idiots and imbeciles; among them, too, there is ome excess of boys, though for different reasons.

The second complication relates to the concept of mental ficiency, which implies a failure in social adjustment rather an simple intellectual retardation. Of those who on account mental backwardness are potentially certifiable only a inority are in fact certified or need to be certified. Thus the rovision for boys and girls respectively in colonies for mental efectives cannot be deduced simply from the distribution of telligence levels. To mention two important differences etween the sexes which affect certification, there are the egitimate babies born to the girls and the greater tendency the boys to come into conflict with the law.

With these reservations, which do not affect the provision of rely educational facilities for the backward, we may consider e effect of the difference between the sexes in dispersion of telligence. Say, for example, it were decided that special hools (or certification under the Mental Deficiency Acts) ould be provided for the dullest 5% of children, and that ilities for special teaching were desirable for the next 5%, n the allocations for this second less-dull group should be % for boys and 4.8% for girls. Suppose that the next 4% ere regarded as suitable for special schools, then these would ed to provide accommodation for boys and girls in the ratio 13 to 11. If the lowest 1% are regarded as equivalent to ose feeble-minded children whose backwardness is such that y may require certification (all these figures, of course, are ected simply as hypothetical examples), then there will be cluded in this fraction 3 boys to 2 girls.

Nature and Origin of the Difference

It is inconceivable that anything in our educational system could be responsible for a big difference in variances combined with an identity of means. It is almost as difficult to imagine that such an effect could be due to any differential influences operating during pre-school life. The source of the difference in variability between the sexes must therefore be inborn; I doubt whether any other possibility would occur to educational psychologists.

It can be concluded that the difference is almost certainly genetic, but beyond that the little that can be said is pure speculation. We know that the heterogametic sex—that characterized by the XY-chromosome pair—diverges more from the common pattern than does the homogametic sex possessing two X-chromosomes. Thus in mammals (the opposite is true in birds), if males are castrated early in life, then development is greatly modified and in bodily characteristics they tend to resemble the female rather than the male. On the other hand, early castration of the female produces much smaller changes. The male is the more highly specialized form, and the higher death rate at practically all ages may be an indication of the cost that this entails. Is a greater dispersion a consequence of the greater specialization? I am not aware of any clear indication of this in regard to physical measurements. For example, Pearl (1940) lists a large number of coefficients of variation. Using this criterion, 60 studies which included both sexes show that males were more variable in 29 instances, females in 31. Of course, in physical measurements interpretation is greatly complicated by the difference in means; it is the identity of the means which makes the analysis so straightforward in the case of general intelligence. Is it to the advantage of the species that in regard to intelligence males should be more and females less variable? It may be so, though it is difficult to see why.

There is little to be said, therefore, except that the difference exists; that a reasonable estimate can be made of its extent; that the practical consequences are of considerable importance; and that the difference, whatever may be the underlying reasons for its existence, is almost certainly genetic. It is to be hoped that future studies will reveal in more detail the mental qualities in which the sexes differ in variability, together with those in which they do not. The study of mental growth may well be facilitated by using our knowledge of this curious phenomenon.

Statistical Appendix

The fitting of the normal curves to the data for the boys and girls of the Scottish and Bath surveys is shown in Table IV.

TABLE IV.—*Fitting of the Normal Curves, Scottish and Bath Surveys*

	Scottish Survey		Bath Survey	
	Boys	Girls	Boys	Girls
n	44,210	43,288	1,742	1,606

Notation: Fisher's *Statistical Methods* (1941).
Units of Grouping: Scottish Survey, 10 points score; Bath Survey, 5 points Otis I.B.

In the published tables of the Scottish survey, the grouping is coarser than is desirable; the effect of this should not be serious, however, and the deductions to be drawn are very unlikely to be materially affected.

A further point about the Scottish figures is that raw scores have been used, uncorrected for age differences. The range of age was 12 months. Trial shows, however, that the variation due to differences in age is very small indeed compared with the variation between children at fixed age. Furthermore, owing to a (non-significant) difference in the regressions, the ratio of the variances when adjusted for age variation does not differ, up to the number of figures used in this paper, from the ratio calculated using the raw scores. Accordingly it seemed simpler to avoid this complication.

The all-important point is the normality of the distribution of general intelligence, for upon this assumption depend any further deductions. It is well known that the frequency distributions yielded by any good intelligence scale are substantially normal. Group-test results, however, are apt to show departures, especially at the extremes. This is to be expected, for in a group test the same set of questions is used for all children, and even at the optimum age of 11 the test tends to be either too difficult to sort out the very dull at one extreme, or not difficult enough to sort out the very bright at the other; both effects are often seen simultaneously. It will be observed that there is a moderate degree of negative skewness in the frequencies of the Scottish survey—this applying to both sexes. This is also true of the boys in the Bath survey; very poor results on the advanced Otis scale, however, were less numerous among the girls, and the tendency to artificial bunching together is so little marked among them that the skewness is negligible. All the distributions are leptokurtic; this is doubtless to be attributed to a failure to spread out the children efficiently at both ends of the scale. Once again the Bath girls show a smaller departure from normality than do the boys.

There is reason to suppose, however, that these departures from normality are due to the construction of the tests and not to any underlying departure from normality in the distribution of general intelligence—at least, until very extreme limits are reached. Well-designed individual scales, which provide for each child a series of tests adapted to its mental abilities, would probably reveal a closely normal frequency curve. The Bath group provides evidence in regard to the lower end. In this group the dullest children on the Otis scale, amounting to about 23% of the whole group, were retested individually on the Stanford-Binet scale, as described in the fourth paper of the series dealing with the Bath experiments (Roberts *et al.*, 1938b). There was no significant departure from normality down to an I.Q. of about 45, which is three and a half standard deviations from the mean—a point outside the range discussed in this paper.

Convincing, even if indirect, evidence regarding the other extreme is provided in Vol. 1 of Terman's *Genetic Studies of Genius* (1925). The figures in Chapter 3 seem to me to give a clear indication that we are taking no undue risk in basing our calculations on the assumption of normality up to the 0.001 point. Terman's whole group of 1,444 included 831 boys and 613 girls, or 136 boys per 100 girls. Terman estimated that his group was about 0.5% of the population sampled. Using the estimate of this paper, the expected number of boys per 100 girls among the brightest 0.5% is 158. Apart from the fact, however, that the brightest 0.5% could not be separated off with complete efficiency, there was undoubted bias in the sampling, as is discussed at some length by Terman. In the light of present knowledge it seems clear that this must have minimized the difference considerably. To give one example, private schools were omitted; and if the effect of this is the same in the United States as it is in this country, it would lead to a heavy disproportionate loss of bright boys.

It is the differences within the sample itself, however, which provide the convincing evidence. Stanford-Binet I.Q.s are given for 1,024 children. Dividing them according to I.Q., the results are as follows:

Stanford-Binet I.Q.	Boys	Girls	Boys per 100 Girls
144–	221	207	107
145–154	206	172	120
155+	132	86	153

Results are also given for 370 children found at high-schools. The overall proportion of boys is much higher, but, once again, within the group the disproportion increases with rising score.

Terman Group-test Scores	Boys	Girls	Boys per 100 Girls
194–	83	53	157
195–204	122	53	230
205+	46	13	354

Whatever the effect of bias in sampling, therefore, upon the composition of the whole group, it is evident that within this highly selected sample of very gifted children the disproportion in numbers of boys and girls increases sharply as intelligence rises, exactly as would be deduced if the consequences of normal dispersion hold up to these extreme limits.

The observed distributions of the group-test results are quite markedly leptokurtic. This has a substantial effect on the variance of the variances; accordingly the estimates of the fourth cumulants have been used in calculating these.

If two series of measurements having the same mean bu different variances are added together it is impossible for al three distributions to be strictly normal. Even at the 0.00 point, however, this leads to a discrepancy of only 3%, so tha the values of Tables I and II are not appreciably affected.

Summary

It is one of the most curious facts in human biology that i regard to general intelligence boys should be considerably mor variable than girls. This is all the more remarkable because ther is no difference in average performance. Girls tend to be groupe closer to the mean for the whole population, boys to spread furthe out into extremes either of brightness or of dullness. Not much ca be said as to the nature and origin of the difference except that is almost certainly inborn. The available data, however, leave n room for doubt as to its reality; furthermore, they are sufficient t yield a tolerably close estimate of its size. Adopting a conservati figure, it is found, for example, that the brightest (or dullest) 1,00 children in every 10,000 will be composed of 534 boys and 466 girls the brightest (or dullest) 100, of 59 boys and 41 girls. At the extrem limits considered, the brightest (or dullest) boy in every 1,000 bo will be matched by only one girl of similar mentality in every 2,0 girls. The consequences in regard to planning both for the brig and for the dull are of considerable practical importance. Tabl are provided from which can be read off the corresponding propo tions of boys and girls to be expected in different portions of th 10% at either end of the range of mentality.

There is not to be any change in the superannuation provisio for nurses and midwives in the service of local authorities, bu separate fund is to be set up for those in the employment voluntary hospitals and approved organizations where the Rushcl and Taylor salary scales have been adopted. This is, briefly, main recommendation of the joint subcommittee for England a Scotland, which has been considering superannuation for nu and midwives (Cmd. 6603, H.M. Stationery Office; 9d.). nurses and midwives to whom the Fund applies must belong, those who are now contributors to the Federated Superannuat Scheme may elect to remain in it. [This latter scheme, which ca into operation for voluntary hospitals in 1928, will remain availa for nurses outside the scope of the new Fund, such as those private practice.] Provision is made for interchangeability v local government schemes, and the benefits recommended under new fund are on a similar basis: minimum qualification fo pension to be ten years' contributing service; retirement compuls at age 60, with the option of retiring on or after 55 on comple of thirty years' service; pension to be based on the average sa and emoluments of the last five years of service and to be at rate of 1/60th for every year of contributing service, subject t total maximum of 40/60ths of such average service; pensions to payable on permanent incapacity on the same basis as for age, v a minimum of 20/60ths and subject to the completion of ten ye contributing service; all salaried service since joining the Feder Superannuation Scheme to rank as contributing service

OBSERVATIONS ON LIGATURE OF THE PATENT DUCTUS ARTERIOSUS

BY

JOHN B. HUNTER, M.Ch., F.R.C.S.

Surgeon, King's College Hospital; Surgeon, Royal Chest Hospital

These remarks are based on the experience gained in 14 cases in which ligation of a patent ductus arteriosus has been performed. Twelve cases were uncomplicated by infection and in only two was endocarditis present. In 10 cases the patients were females, and the ages varied between 5 and 31 years. In the non-complicated cases the patients were all slightly stunted in growth and the majority were breathless on exertion, but only one showed any signs of cyanosis.

Method

The operative technique was similar in all cases. The approach was that described by Gross. The patient is placed on his back with a small sandbag under the left shoulder and upper part of chest, with arm extended above the head, thus allowing a slightly left lateral approach to the mediastinum. An incision is made along the second intercostal space, curving upwards to the axilla. It is found that splitting the pectoralis major rather than cutting it across gives sufficient access. The pleural cavity is opened through the second space and the second costal cartilage divided obliquely close to the sternum; in most cases the internal mammary artery is not interfered with, but if it is injured it can easily be ligatured. After the pleura is opened a single rib-spreader is introduced; the lung collapses away from the mediastinum and is lightly packed off with a gauze roll. In only one case were adhesions found between the lung and mediastinal pleura, and these were readily separated. On the mediastinal wall the phrenic nerve can be seen shining through the pleura, and an incision is made in the pleura parallel with the nerve and about an inch below it. There is a marked difference in the access to the operative area in children and adults: in the latter the arch of the aorta is much higher and is situated more deeply, thus increasing the difficulty of the operation; while in children the arch and pulmonary conus are immediately beneath the second space and the operative area is readily accessible.

After making the pleural incision it is advisable to clean the inner surface of the pleura on the lower side before increasing access to the mediastinum, as by doing so any small veins that may be present are separated, and these, falling away into the lax tissue, cause no further trouble or, if they have to be dealt with, can be picked up more readily and ligatured.

Blunt dissection backwards and upwards towards the arch of the aorta discloses the recurrent laryngeal nerve tightly winding round the aorta, and running more from right to left than is realized. This landmark immediately indicates the upper and posterior point of the ductus, and by working down to the pulmonary artery the left edge of the ductus is defined. The anterior and the right edge are more difficult to dissect out; at first sight there appears to be no space between the pulmonary artery and the inner surface of the arch of the aorta, but by slow blunt dissection a space is determined and the right border of the ductus defined. There seems to be considerable variation in the upward prolongation of the pericardium at this point, and in several cases fluid was present in the pericardium. When this occurs the pericardium, which is thin at this point, tends to bulge slightly into the operative area and obscure the view. In one case the pericardium was punctured and fluid oozed into the mediastinum throughout the operation.

The ductus itself, when defined, is very short and runs much more antero-posteriorly than one expects. Gentle traction with a finger on the pulmonary artery helps very considerably to define the ductus, allowing the operator more readily to free the posterior surface. This has to be done with great care by gently passing curved forceps behind it, as it is at this point that the ductus may be torn. In one of my cases this apparently happened towards the end of the dissection, but I was able to place the ligatures round the ductus, which stopped the bleeding.

When the ductus has been defined, pressure on it stops the very marked thrill of which the operator has been conscious throughout the proceeding. It is stated that the flow of blood through the ductus is from the aorta to the pulmonary artery; one would therefore expect that the amount of pressure to obliterate the ductus would be similar to that required to obliterate any artery. This, however, is not so: very light pressure, such as suffices to obliterate a vein on the back of the hand, is all that seems necessary, suggesting that the pressure in the ductus must be low and the blood flow may be from the pulmonary artery to the aorta, this being permitted by the eddy in the concavity of the arch. In one case the ductus was so thin that blood could be seen through the wall, and the flow appeared to be from the pulmonary artery to the aorta; but this point requires further investigation.

The ductus being freed, an aneurysm needle is passed and, contrary to Gross's views, I prefer to pass it from left to right. Care has to be taken that the recurrent laryngeal nerve is kept away from the ligatures, which is usually quite easy as the nerve is wrapped so closely round the aorta. No. 8 silk is used as ligature material, and it is waxed so that it runs easily. The moment the first ligature is tied the thrill disappears; in one case the ductus was so large in diameter and short in length that after tying the second ligature the first was found to be quite slack, and it had to be removed and another placed in position.

The incision in the mediastinal pleura is then sewn up and the lung re-expanded by positive pressure. A catgut suture is passed through the cut ends of the costal cartilage with a cutting needle—approximating the cut edges of the cartilage and preventing the unsightly appearance of an overlapping cartilage—after which the intercostal space is closed with sutures.

The rest of the wound is sutured with care, as unfortunately this particular incision tends to heal with an unsightly scar. In the last cases I have made the skin incision curve downwards almost to the nipple and then upwards to the anterior axillary line, and the subsequent scars have been less unsightly. The left upper arm is lightly bandaged to the side of the chest wall for 24 hours to prevent movement of the pectoralis major.

The convalescence of the uninfected cases was uneventful with the exception of one (Case 12). A radiograph on the third day usually showed the pressure of a small pneumothorax at the apex, and in some cases a little fluid. Both these were rapidly absorbed, and the patients were allowed to sit up in about 14 days; children were allowed up earlier.

Case 12 requires special note. This patient was an undersized girl of 5½ who was in hospital for some little time before operation and had her adenoids removed about three weeks before the ductus was tied. The operation was uneventful and the child was allowed up on the sixth day. On the tenth day she had a temperature of 102°, which persisted without any apparent cause. A blood culture showed a pure growth of *Staph. aureus*. She was transferred to the penicillin ward of the Middlesex Hospital, and after treatment the temperature fell; subsequently it rose again, and a fresh blood culture produced a staphylococcus that was resistant to penicillin, and she eventually died. This case calls for a serious review of the procedure, but after careful consideration of all the facts I do not think that the operation can be held responsible; if anything, the argument for ligation is strengthened, as these patients with a patent ductus appear to be liable to start an endocarditis after an infection that is of little or no consequence in the normal person. The two infected patients both died. In one sulphonamide drugs had little or no effect; in the second they controlled the temperature for short periods only and eventually ceased to act.

It is too soon to say what the ultimate fate of these cases may be. One of the children is now taking up tap-dancing as a profession; the young male (Case 1) has been accepted for the Services. The others have lost their breathlessness on exertion, and the earlier ones that have recently been reviewed have improved in general health and physique.

It would seem that there is a case for the tying of an uncomplicated patent ductus. The risks attending such a persistent deformity have not yet been accurately assessed, but that there is a definite risk of infection which has a grave prognosis is unquestionable. Apart from this, however, the tying of the ductus restores the patients' circulation to normal, breathlessness disappears, there is a marked improvement in their appearance, and a noticeable change for the better occurs in the mental condition. The last-named improvement is noticeable in the youngest patients, who from rather "solemn little owls" become bright and cheerful children.

Notes on Cases

Case 1.—Male aged 16. Admitted 2/12/41; discharged 23/5/42. Rejected by medical board on discovery of albuminuria and an abnormal heart. No symptoms. No evidence of circulatory inefficiency. Continuous murmur to left of sternum in pulmonary area. B.P. 140/75. Albuminuria was transient, and was never detected after the operation. A patent ductus was ligated on 14/3/42.

Case 2.—Girl aged 18. Admitted 5/5/42; discharged 12/7/42. Referred from medical board for morbus cordis. Harsh murmur and thrill throughout cardiac cycle in 2nd and 3rd left interspaces. B.P. 120/70. No evidence of circulatory failure. E.C.G. normal. Considered to be a case of uncomplicated patent ductus. Ligated on 2/6/42; uneventful convalescence.

Case 3.—Married woman aged 26. Admitted 15/6/42. Died. Known to have had congenital heart disease all her life. Activities always reduced. Pyrexial illness and increasing dyspnoea dating from tooth extraction two months before admission. Examination showed incipient circulatory failure; heart enlarged; murmur of patent ductus and loud systolic at apex. Early finger-clubbing. Positive blood culture of non-haemolytic streptococcus. Diagnosis: subacute bacterial endocarditis on a patent ductus; this was ligated on 19/6/42. Within a month after operation there was evidence of aortic valve involvement. Deterioration was rapid and death occurred two months after operation. Necropsy revealed extensive vegetation on the pulmonary artery and on the pulmonary valves.

Case 4.—Girl aged 10. Admitted 9/7/42; discharged 8/8/42. Complained of asthma since age of 4. Known to have had congenital heart disease since 6 months old. Pale and under-developed child. No symptoms or signs of inefficient circulation. Characteristic patent ductus murmur and thrill in 3rd left interspace. Ligation on 26/7/42.

Case 5.—Married woman aged 31. Admitted 28/8/42; discharged 31/10/42. Many years' history of dyspnoea on slight exertion, activities being considerably limited. Heart not enlarged; systolic thrill and continuous murmur in pulmonary area. B.P. 120/85. No circulatory failure. Radiograph revealed enlarged pulmonary artery. E.C.G. normal. The patent ductus was ligated on 29/9/42. Convalescence was uneventful.

Case 6.—Spinster aged 25. Admitted 9/9/42; discharged 23/10/42. Rejected from military service because of presence of patent ductus arteriosus. She had experienced rather more dyspnoea than is normal on exertion, but there were no other symptoms suggestive of her disease. The ductus was ligated on 24/9/42, after which the typical murmur entirely disappeared. Convalescence was uneventful.

Case 7.—Girl aged 9. Admitted 3/11/42; discharged 6/12/42. This girl had not experienced any abnormal symptoms, but was pale, slight, and asthenic, weighing only 3 st. 12 lb. A typical machinery type of murmur was heard in the pulmonary area together with a thrill. She had a low diastolic pressure. B.P. 120/55. An E.C.G. showed a normal curve, and a radiograph slight prominence of the pulmonary artery. The patent ductus was ligated on 19/11/42, after which all physical signs disappeared. Convalescence was uneventful.

Case 8.—Girl aged 12. Admitted 2/3/43; discharged 18/4/43. This patient complained of palpitations and breathlessness on mild exercise. The symptoms were relatively slight and she always felt well apart from breathlessness. At school she took part in swimming and physical training. She was well built. Her heart was normal in size. B.P. 135/70. Murmur was hardly a continuous one in the pulmonary area, being scarcely audible in diastole. No thrill was palpable. Ligation of the patent ductus was done on March 23, after which she had an uneventful convalescence, apart from a small hydropneumothorax. There were no abnormal physical signs in the heart.

Case 9.—Girl aged 21. This patient was admitted with a history of prolonged inactivity due to dyspnoea and exhaustion on exercise for at least seven years. She was well built, and examination showed no signs of heart failure. There was a loud continuous murmur in the pulmonary area accompanied by a thrill. No other signs of an additional congenital lesion were observed. The patent ductus was ligated on 6/4/43; the murmur was quite inaudible afterwards, and her convalescence was uneventful.

Case 10.—Boy aged 6½. This boy was quite fit on admission, but was small for his age. He had been followed up for some time on account of patent ductus arteriosus, but there was no evidence of disability from this. Examination revealed a characteristic to-and-fro murmur, but there was no thrill over the 2nd left interspace. Ligation of the ductus was carried out on 13/8/43. His convalescence was completely uneventful, and the heart sounds were subsequently normal. This case is particularly noteworthy for the extremely small amount of disturbance which the operation caused. The boy was up and running about within a week.

Case 11.—Boy aged 5½. The patient had had dyspnoea on exertion for a period of about a year and failed to grow. He was an undeveloped child—height 43½ in., weight 35½ lb.—slow in speech but mentally normal. Pulse 110, regular rhythm; no clubbing; typical murmur running right through systole and diastole, best heard in pulmonary area; slight right-sided hypertrophy. Temperature normal; no evidence of infection. Radiograph showed very slight dilatation of pulmonary artery but no general enlargement. Ductus ligatured on 18/3/44: small ductus, about 1/4 in. The murmur had gone entirely after operation. On the evening of operation there was a small pneumothorax on the left side, and the next morning some surgical emphysema on the left side of the chest. These signs soon cleared up. Discharged on 30/3/44, symptom-free, left lung well re-expanded.

Case 12.—Girl aged 5½. Admitted 27/8/43 with an uncomplicated patent ductus arteriosus. Owing to the presence of some pharyngeal sepsis, adenoidectomy was performed on 24/9/43. After this she was very well, and was considered fit for operation. On 12/10/43 the ductus was ligated and found to be about 1/3 in. in diameter. Immediate post-operative convalescence was good, but on the ninth day she had sudden pyrexia, which subsequently proved to be due to a *Staph. aureus* septicaemia. This failed to respond to sulphathiazole and later to penicillin. She subsequently died on 24/12/43. No necropsy was performed.

Case 13.—Girl aged 20. Admitted 7/2/44. Was known to have had a patent ductus since shortly after birth. She had been well until about three weeks before admission, when she had an attack of "pneumonia." As her temperature did not settle she was seen by Dr. Morland, who diagnosed a septic infarct. On admission a blood culture gave a profuse growth of *Str. viridans*; after a blood transfusion and a course of sulphathiazole her temperature appeared more controlled. The ductus was ligated on 8/3/44, and after two days her temperature, which had been 103°, was again controlled by sulphonamide drugs. When these were discontinued the temperature rose again and she had a further infarct. Her condition then slowly got worse; she had infarcts in the kidneys and later in the brain.

Case 14.—Boy aged 7. Admitted 30/10/44. This boy had previously been seen, in consultation with Dr. Sheldon, when he was running a temperature thought to be due to endocarditis; but there was no growth on blood culture and his temperature reacted to a course of sulphonamides. He subsequently had his tonsils removed after a prophylactic course. It was decided that in view of his previous illness he should have his ductus ligatured; this was done on 4/11/44, and he was given a further course of sulphathiazole before and after operation. The ductus showed no evidence of old infection. He made an uneventful recovery, and was discharged on 21/11/44.

Dr. M. D. Nosworthy was the anaesthetist for all these cases. The anaesthetic was closed cyclopropane and ether. Blood-pressure readings and pulse rates were taken by him during the operation; no consistently demonstrable changes in pulse rate or blood pressure were recorded when the ductus was tied.

I wish to thank Dr. East, Dr. Sheldon, Dr. Maxwell, Dr. Cedric Shaw, Dr. Courtney Evans, and Dr. Andrew Morland, who have sent me the cases recorded; also Dr. Brigden, who has collected most of the case notes.

A. Odusanwo), on the canals of Britain (by Ruth Layton), and in Cairo (Jeanne Marie Small). Dr. E. H. M. Milligan puts forward an idea for a "child international" to unite all child welfare organizations in Britain and the world, and the editor pleads for greater development of child education through the film, as was attempted in France before the war and is now being encouraged in the U.S.A.

PSYCHOTIC BATTLE CASUALTIES

BY

E. K. MULINDER, M.B., Ch.B., D.P.M.
Capt., R.A.M.C.

Neurosis arising from battle stress has been repeatedly investigated in the last five years. Psychosis precipitated in the same way is rarer but more interesting, and has largely escaped attention. The object of this article is to classify cases of psychosis induced by stress of battle, and to give examples which, though psychotic, differ from the classical types of psychosis both in their clinical forms and in their duration, which is temporary.

Cases admitted to the psychosis ward of a British psychiatric hospital in Normandy during a period of fierce fighting have been classified as follows:

			No. of Cases
1. Psychoses of classical type, unrelated to battle stress			11
2. Psychoses precipitated by battle stress, but clinically indistinguishable from Group 1			36
3. Temporary psychoses precipitated by battle stress and differing from recognized types:			
A. Reactions to stress and fear:			
(i) Showing confusion	35	52	91
(ii) Showing regression	5		
(iii) Acute anxiety states	12		
B. Reactions to awareness of failure to tolerate the stresses of battle	17		
C. Reactions to death of comrades	22		
Total			138

Discussion is confined to cases in Group 3, of which the following typical examples are given.

A. Reactions to Stress and Fear

(i) *Showing Confusion.*—Tpr., aged 29; service 4 years. The family history was negative, and the personality stable prior to Army service. He had seen much service as a tank driver in the Middle East. In 1942, after severe battle stress, he suffered from "loss of memory" for a week. On account of this and otitis media he was transferred to the fitters' workshop. In Normandy he was again employed as a tank driver. He continued duty for a month, taking part in several attacks before he broke down.

On admission he was confused and disorientated. He showed no fear, but was euphoric, irritable, easily annoyed, and was rambling and garrulous. He completely misinterpreted objects and events about him, to conform with his belief that he was still in the midst of a battle. His memory was very poor for both past and recent events. During the first week he gradually improved, becoming orientated and recovering his memory almost completely. He eventually became willing and fit to return to his earlier employment as fitter.

(ii) *Showing Regression.*—Pte., aged 25; service 9 years. This man passed down the line of evacuation and was admitted in a stuporous state, clutching a doll in his arms. He lay curled up in bed like a child, clinging to the doll as a drowning man to a straw. If approached or addressed he showed extreme terror, and tried to hide under the bedclothes. On the fifth day he became lucid and accessible. He stated that a mate who had been killed had obtained the doll for his children. The psychotic withdrawal was replaced by symptoms of an anxiety state.

(iii) *Acute Anxiety States.*—Pte., aged 27; service 9 years. This patient had had an unhappy childhood: his parents had separated, and he had been reared by a drunken foster-mother. His previous personality was stable. He had been employed as a mess waiter, but in the invasion was used as an infantryman. He had been in action for four weeks since D day, when a shell landed on the edge of his trench. He broke down into a state of terror and confusion.

On admission he was in a condition of extreme terror, believing that a Messerschmitt was after him all the time. He interpreted every sound as an approaching plane or shell. His pupils would then dilate; sometimes he tried to run away, and at other times would bury himself in abject terror beneath the bedclothes. After three days of gradual improvement he became lucid. The condition was then one of acute anxiety: he was easily startled, and complained of headache aggravated by noise.

B. Reactions to Awareness of Failure to Tolerate the Stresses of Battle

Sgt., aged 21; service 4 years. There was nothing relevant in the family or personal history. He had volunteered, and had served in Iceland. He had been in action in Normandy for five weeks. He had felt increasingly anxious, and finally became panicky and uncontrollable; he was also depressed, with a strong suicidal tendency.

On admission he gave a clear account of himself, except for a period of two days when he had been in a field dressing station in a confused and depressed state. He was miserable, solitary, and self-reproachful. He asked to be left alone, as he considered himself unworthy of attention when so many better men than he had been killed. With the help of treatment he became much less depressed during the next few days, but remained in a state of moderate anxiety.

C. Reactions to Death of Comrades

Tpr., aged 20; service 2 years. There was nothing relevant in the family or personal history. He had served satisfactorily as a tank driver in Normandy for eight weeks. Then his tank, going far forward on a reconnaissance, was hit, and the tank commander was killed by an 88-mm. shell. The patient, after further severe stresses, was rescued: he was then stuporous.

On admission he was depressed and semi-stuporous, with some agitation. He was almost mute, but it could just be ascertained that he thought he was responsible for his tank commander's death, and that he could hear accusing voices. During the subsequent week he improved considerably, but remained mildly depressed. He tended still to blame himself, and lacked self-confidence.

Discussion

Cases in Group 3 do not fit readily into any established classification of psychoses. These patients are considered psychotic because they show a marked detachment from reality, together with various combinations of other typical characteristics, such as confusion, mutism, delusions, hallucinations, psychomotor retardation, flexibilitas cerea, depression, or elation.

The cases differ from the classical forms of psychosis in several ways: they usually arise in men with good family and personal backgrounds; the condition is precipitated by severe and usually prolonged stress; the prodromal symptom is a sense of increasing anxiety, but this is not always present. The content of delusions, hallucinations, or emotional disorder is derived from experience immediately before the breakdown, and is less fixed and more accessible to reasoning than in the typical psychotic. The most notable difference is in the duration: the psychotic manifestations improve steadily, and disappear with striking suddenness at the end of three to seven days. Symptoms of neurosis, usually an anxiety state, are subsequently presented, often after a lapse of a day or two, during which the patient has no complaints and appears contented. This group thus forms an interesting link between the psychoses and the neuroses.

Treatment for the first few days consisted of rest, reassurance, and just enough sedation to ensure sleep at nights. During the day, especially as improvement occurred, every effort was made to restore contact with reality and to correct misinterpretations of surroundings. In the stage of recovery the patient was encouraged to recall his battle experiences fully. Where necessary, an intravenous injection of pentothal sodium was used to facilitate this abreaction of traumatic incidents.

Summary

A series of 138 psychotic casualties arising in the Battle of Normandy have been classified.

Attention is drawn to a psychosis of short duration and distinctive clinical form which was present in 91 of these cases.

The special features of this psychosis are: (*a*) sudden onset after battle stress in men with good family and personal histories; (*b*) typical psychotic detachment from reality, with other psychotic manifestations such as confusion, delusions, and hallucinations; (*c*) rapid recovery from the psychotic state, usually within one week; (*d*) subsequent development of neurosis.

Treatment consisted initially of rest and reassurance. Later, the traumatic battle experiences were brought back into full consciousness.

I wish to thank Col. R. J. Rosie for permission to publish this report on cases seen in the hospital under his command.

C. M. Tinsley (*Arch. intern. Med.*, 1945, **75**, 82) states that pneumococcal endocarditis occurs in about 3% of all pneumococcal infections and is responsible for about 5 to 10% of deaths due to pneumococcal infections. The aortic and mitral valves are infected in 36 and 33% of the cases respectively. Purpura, splenomegaly, and infarction are less common than in subacute bacterial endocarditis. The disease is usually rapidly fatal.

ACUTE INTESTINAL OBSTRUCTION DUE TO DRIED FRUIT

A REPORT OF TWO CASES

BY

ALEXANDER LYALL, M.D., Ch.M.Glas., F.R.C.S.Ed.

Surgeon, Royal Infirmary, Greenock

The impaction of a foreign body is a rare cause of acute intestinal obstruction—according to Handfield-Jones and Porritt (1943) in 0.3% of the cases. The following cases, which were due to the ingestion of dried fruits, are worth recording.

Case I

A soldier aged 37 was admitted to hospital with signs of acute intestinal obstruction. Abdominal pain had begun about 24 hours previously. It was not very severe at first, but had latterly increased in intensity, and when seen by us the patient was having very marked attacks of intestinal colic, with much effortless vomiting. Dehydration was present, and an intravenous saline drip was started.

Operation was carried out two hours after admission. The abdomen was opened by a right paramedian incision in the lower region. There was a small quantity of clear fluid in the peritoneal cavity. The small bowel was very distended and the dilated loops were followed down to a point about 5 feet from the ileo-caecal valve. At this point there was a mass of firm material completely blocking the lumen of the gut. The bowel beneath was contracted and empty. With some difficulty the foreign material was pushed along the ileum and finally through the ileo-caecal valve into the colon.

The patient made an uninterrupted recovery, and three days later passed the foreign body. It consisted of a piece of vegetable-like material measuring 1½ in. by 1 in. by 1 in. The pathologist could not identify the exact nature of the vegetable, but the patient admitted, when questioned, that he had been eating dried fruits on the evening before the onset of the pain and that he had swallowed some of the pieces without chewing them very well, as he had been very hungry.

Case II

A cookhouse boy in the Merchant Navy, aged 16, was admitted to hospital in a comatose condition, and died soon after admission. The history stated that he had not felt very well when he arose that morning and had taken no breakfast. In the forenoon, about 7½ hours before his death, he had developed severe abdominal pain, which came in spasms and caused him to roll about his bed. When seen by the medical officer some hours later he had slight diffuse abdominal tenderness, but there was a point of extreme tenderness in the lower abdomen just to the left of the midline. The patient had vomited fairly large quantities of clear fluid. When seen by us the boy was comatose and showed signs of extreme dehydration. There was moderate abdominal distension. Preparations were quickly made for intravenous therapy, but he died before these were completed.

A post-mortem examination was carried out the next day. The body was that of a well-nourished youth. The abdominal cavity contained a quantity of slightly blood-stained material. The stomach and small bowel showed extreme dilatation. This distension was followed down to a point 6 in. above the ileo-caecal valve, where there was a mass of hard substance completely blocking the lumen. On opening the bowel two large pieces of apple were removed. One of them measured 3 in. by 1 in., and showed four small tooth-cuts which went through only a part of the thickness of the substance. The other piece measured about 3/4 in. square, and had no tooth-markings. The small intestine above the obstructed area had some blood-stained material in it, but in an upward direction the contents became whitish yellow in colour right up to the stomach, which contained a little grey material and much gas. The other organs of the body showed no abnormality.

Careful examination of the foreign bodies confirmed that they were pieces of dried apple which had swollen in the intestinal tract. Inquiries showed that the boy, who assisted the cook, had access to dried apple, which was being used at that time.

Comment

These two cases show the danger attaching to the ingestion of dried fruits without thorough mastication and unless they have been properly cooked. In the first the patient appeared to have "bolted" an excessively large piece of the cooked material. In the second case it seemed to be impossible for the boy to have swallowed such a large mass, and our inquiries showed, in fact, that there had been no official meal of the dried apples for some days beforehand; this suggested that he had actually eaten the untreated dried apple from the store, that he had found difficulty in chewing it, and that the fruit had become greatly swollen in the presence of the moisture in the intestinal tract and caused complete obstruction. The early collapse and death suggested that the obstruction had probably started primarily much higher in the small intestine than the position of the foreign matter suggested at necropsy. The very acute nature of the process was shown by the blood-stained material in the peritoneum.

Medical Memoranda

A Series of Unrelated Pathological Conditions in One Case

The findings in the post-mortem examination recorded below are unusual enough to warrant publication.

CASE HISTORY

The patient, a woman aged 49, had had no occasion to consult a doctor for eight years, but immediately before death, which was sudden, had complained of a pain between the scapulae. At necropsy the body was well nourished, but the general appearance was of a woman of 60. Externally there was nothing to indicate the cause of death. On opening the thorax the pericardium was seen to be full of blood. There was a tumour pushing up the diaphragm on the right side: this protuberance was about 3 in. in height from the level of the rest of the diaphragm, and its base was about 9 in. in circumference. There was a similar but smaller upward bulge of the diaphragm on the left side. On opening the abdomen these tumours were found to be herniae of the liver covered by a thin sheet of muscle. They were not neoplasms, but were protuberances of normal liver tissue.

The pericardium was then opened, and a small aneurysm of the ascending and transverse portion of the aortic arch was found to have ruptured into it. There was no free blood in the pleural cavities. The aneurysm was of the dissecting type, and had separated the coats of the aorta as far as a point about 2 in. above the diaphragm.

On opening the heart a well-marked degree of mitral incompetence was found: the endocarditis was evidently ancient history, for the lesions on the valve cusps were firmly fibrosed and organized. The heart muscle was hypertrophied and firm, without signs of dilatation. The aorta was atheromatous; the innominate, left carotid, and subclavian openings were all dilated and rigid; while the coronary vessels were atheromatous, dilated to double the normal size, and projected from the cut surface of the heart muscle.

The abdominal organs showed chronic venous congestion and the spleen was enlarged. The left renal vessels were dilated, the vein admitting a lead pencil with ease. The right kidney was small, but the vessels supplying it were also enlarged in relation to its size. Finally, there was a diverticulum of the jejunum about 12 in. below the duodeno-jejunal junction.

Microscopically the spleen showed replacement of pulp by fibrous tissue. The Malpighian bodies were prominent. There was well-marked endarteritis obliterans. The kidney showed a similar condition of the blood vessels, with degeneration of the Henle and convoluted tubules.

Oranges causing Alimentary Obstruction

The following two cases of alimentary obstruction caused by oranges may be of interest.

CASE I

A silicosis pensioner aged 56 was admitted to this hospital on Jan. 21, 1945. He gave the following history. At 8 a.m., 14 hours before admission, he was seized with an attack of colicky abdominal pain. This passed off, but recurred at intervals of a few minutes during the day. He had a normal motion in the morning. He ate some dinner, but immediately vomited it. He did not vomit again until after admission. The pain spread across the middle of his abdomen from right to left.

On examination the tongue was furred and the breath rather offensive. T. 98°, P. 80, R. 24. The patient did not look ill. The abdomen was slightly distended; there was tenderness over the whole of the right side of the abdomen. Guarding was generalized except in the left iliac fossa. Peristalsis was vigorous, with loud borborygmi. There was no rectal tenderness.

A diagnosis of small-bowel obstruction was made and laparotomy performed. On opening the peritoneum a little free fluid was found. The small intestine presented, engorged and distended. The whole of the jejunum and about a foot of the ileum were thus affected; the rest of the bowel was collapsed. At the junction of the two portions was felt, within the lumen, a semi-solid body containing a few hard lumps; it was about 1 in. in diameter. It was milked down to a healthy part of the ileum and removed by opening the bowel. The cause of the obstruction was seen to be a white object, which opened, revealing itself to be the pith of half an orange with some pips. The patient made an uneventful recovery.

CASE II

A pit engine-man aged 66 came to the out-patient department on Dec. 18, 1944, with the story that for a week he had been able to swallow fluids only. Solids would stick when half swallowed and were regurgitated. He had lost some weight and complained of weakness, and his appetite was poor. No previous history of dysphagia; no voice changes.

On examination he was rather thin—in keeping with his story of a week's starvation. There were no signs of anaemia, and no cervical glands were palpable; the thyroid was normal; laryngoscopy showed no signs of disease. Respiratory and other systems appeared normal. A barium swallow revealed a hold-up at the lower end of the oesophagus, rather suggestive of malignancy. There was no dilatation of the proximal part. Oesophagoscopy on Dec. 29 revealed a white foreign body lodged at the lower end of the oesophagus, which appeared inflamed. As it was too large to pull through the tube the oesophagoscope and mass were withdrawn together. On close examination the foreign body was seen to consist of the rolled-up pulp of half an orange. The oesophagoscope was then passed easily to the cardiac orifice. Apart from some inflammation at the level of the obstruction, the oesophagus appeared normal.

Next day the patient was able to take an ordinary diet with scarcely any discomfort. A barium meal shortly afterwards revealed a suspicion of either malignancy or ulceration at the cardiac end of the stomach. Since discharge the patient's condition has been satisfactory.

Our thanks are due to Dr. H. M. N. Calder and Mr. R. S. Venters, respectively, for permitting us to publish these cases.

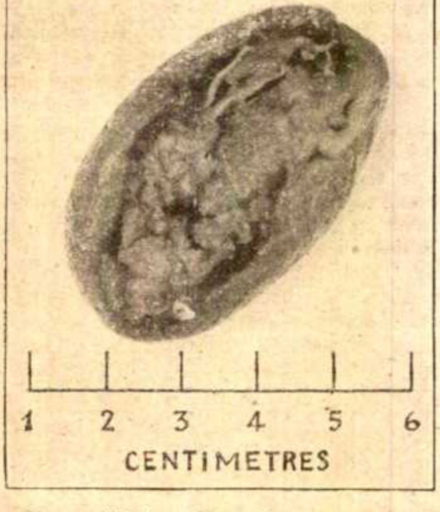
Whitehaven and West Cumberland Hospital.

Intestinal Obstruction by a Foreign Body

In view of the recent importations of dried fruits from abroad there is quite a risk of intestinal obstruction following the ingestion without mastication of large morsels and their subsequent swelling in the alimentary tract. Although the present case relates only to an ordinary orange, the further possibilities of such cases should be kept in mind.

CASE REPORT

A woman aged 60 was admitted on the evening of Feb. 24, 1945, to the Derby City Hospital with a history of acute epigastric pain and continual vomiting since 11 p.m. the day before. Her bowels had last acted the previous morning. Examination revealed no distension of abdomen, but faeces in the rectum and a moist tongue. There was a small mass to the left and above the umbilicus, probably omentum in a para-umbilical hernia. This did not seem sufficient cause for her acute distressing symptoms, and after being placed on intravenous glucose-saline a laparotomy was performed. There was an obstruction due to an oval-shaped mass in the ileum about 2 feet from the ileo-caecal valve. This was removed and the intestinal wall repaired. The para-umbilical hernia was found to have spontaneously reduced itself. Examination of the mass (see Fig.) showed it to be half an orange.



The patient has artificial teeth, but they are not used because she cannot "master them." She vigorously denies swallowing part of an orange, but admits to sucking a half of one about 26½ hours previous to the appearance of symptoms.

I wish to thank Sgt. Fayres for taking the excellent photograph.

City Hospital, Derby. LEON RADCLYFFE, M.B., B.S.

Sulphonamide-resistant–Penicillin-sensitive

Just as bacteriological findings elucidated the treatment of empyema and explained the disasters after draining streptococcal effusions, so the dawn of penicillin with new rays of hope may help in cases of appendicitis where the streptococcal nature of the infection is known early enough and cultures show the sensitivity to sulphonamides and penicillin. This point is illustrated in a case of streptococcal subphrenic abscess following perforated gangrenous appendicitis recently admitted under my care.

CASE REPORT

A schoolgirl aged 16 was admitted to the Gloucestershire Royal Infirmary on Dec. 3, 1944, with the following history: On Nov. 30 she slipped in the mud when playing netball, and in the afternoon complained of severe pain in the right loin. This was followed by sickness during the night. The doctor called in suspected contusion of the right kidney. On the morning of Dec. 3 her condition was obviously serious and she was transferred to hospital. On admission her temperature was 101.8° and pulse 106, and the tongue was furred. She was tender in the right iliac fossa and the right loin and was resistant. Acute appendicitis was diagnosed, and an operation was performed immediately.

A muscle split incision revealed foul-smelling pus. The appendix was felt retrocaecally, but was not disturbed, and a wide drain was introduced. A course of sulphathiazole was given for five days, but her temperature remained between 100° and 102° and her pulse rate varied from 104 to 136 for two weeks. There was little discharge from the wound, but a faecal fistula developed, which closed after 10 days. There were no signs at the base of the right lung to suggest an abscess below the diaphragm and no collection could be felt either in the abdomen or in the right loin. There was, however, tenderness over the last rib. An *x*-ray examination with a portable apparatus was inconclusive. Sulphadiazine, 2 g. four-hourly, was administered at this stage, but though tolerated well did not influence the case clinically.

On Dec. 20 subphrenic abscess was suspected so strongly that exploration was decided upon. The twelfth rib was resected and an abscess between the liver and the diaphragm was evacuated by separating the liver from the thoracic wall. This was drained with a split tube. On Dec. 22 there was no improvement in her general condition, as would have been expected after drainage, but this was explained by Dr. E. N. Davey's report on the cultures of the pus—a growth of *Str. viridans*, which was sulphonamide-resistant but penicillin-sensitive. Dr. Davey advised immediate treatment with penicillin locally and systemically. This was carried out under his supervision.

The abscess cavity was injected with 2,500 units of penicillin four-hourly, and a solution of penicillin in saline (100,000 units per 1/2 litre) was introduced into the outer side of the thigh intramuscularly daily for 4½ days. On Dec. 23 her condition was critical, her pulse rate being 140, and she refused fluids.

The next afternoon there was a dramatic improvement in her condition. She was eager for her food and had obviously turned the corner. Her progress has been steadily maintained. Cultures from the wound on Dec. 24—48 hours after giving penicillin—grew a light growth of *Str. viridans*. After a further 48 hours the cultures were sterile.

COMMENTS

The knowledge that the cultures were sulphonamide-resistant and penicillin-sensitive undoubtedly saved this patient's life, for without it the permission to use penicillin would not have been granted. The effects of the penicillin were not obvious for 48 hours. It is clear, therefore, that there is no time to lose, and penicillin should be available immediately.

DR. E. N. DAVEY'S COMMENTS

This case stresses the importance of making a bacteriological examination of pus in all cases of infection, no matter how obvious the type may appear. The foul-smelling pus at the primary operation no doubt suggested a coliform infection, but, in view of the finding of streptococci in the subphrenic abscess, it raises the question as to the exact nature of the appendicular infection at the outset.

The necessity for the bacteriologist not only to report the nature of the organism but also to assess the sensitivity of the microbe to sulphonamides and to penicillin is also made evident, so that time and useless application of these new methods of treatment may be saved.

A difficulty in the application of penicillin treatment seems to be to ascertain when it is safe to discontinue its use. In this case we were guided (1) by the clinical improvement as shown by the return of pulse and temperature to normal; (2) by the fall of the leucocyte count from 16,600 per c.mm. (85% polymorphonuclears) at the time of the subphrenic abscess, collected on Dec. 16, 1944, to 8,600 per c.mm. on Dec. 27, 1944; and (3) by rendering the discharge from the wound sterile.

My thanks are due to Dr. Cairns Terry, physician, and Dr. E. N. Davey, pathologist, to the Gloucestershire Royal Infirmary, for their co-operation in this case.

ARNOLD ALCOCK, M.B., B.S.,
Surgeon to the Gloucestershire Royal Infirmary.

Reviews

THE FOETAL CIRCULATION

The Foetal Circulation and Cardiovascular System, and the Changes that they Undergo at Birth. By Alfred E. Barclay, D.M., F.R.C.P., Kenneth J. Franklin, D.M., F.R.C.P., and Marjorie M. L. Pritchard, M.A. (Pp. 275; illustrated. 50s.) Oxford: Blackwell Scientific Publications. 1944.

The larger and more important section of this book consists of a collation of the authors' researches carried on during the last seven years at the Nuffield Institute of Medical Research, Oxford. The technique adopted was a novel one. A foetal lamb near full term was delivered by Caesarean section. With respiration prevented, an intravenous injection of a contrast medium such as thorotrast or perabrodil was immediately made and the course of the latter in the foetal circulation was demonstrated by cineradiography. That recording was begun in some cases in less than thirty seconds after delivery speaks highly for the team's speed and dexterity. The results of their observations fall into two groups: the actual course of the foetal blood flow and the circulatory changes which occur at birth. With regard to the former, the authors confirm the view which was first enunciated clearly by Sabatier some 170 years ago and which since then has been a matter of such frequent controversy. The blood reaching the right atrium from the inferior (or posterior) vena cava passes for the most part through the foramen ovale (the via sinistra in the authors' idiom), while only a small portion of it reaches the right ventricle. In contrast to this, the blood returning through the superior (or anterior) vena cava passes in its entirety through the tricuspid orifice. Further, this method showed the rapidity with which at birth the foramen ovale, the ductus arteriosus, and the ductus venosus are functionally closed. Four minutes suffice for the ductus arteriosus, five to twenty-five minutes for the ductus venosus after ligation of the cord, while in just over five minutes after the first respiration the foramen ovale is no longer physiologically patent.

A criticism that many anatomists are likely to make of this part of the book is that the introduction of several fresh terms for old familiar ones—e.g., "crista dividens" for the annulus ovalis or "pars libera viae dextrae" for the Eustachian valve—is unnecessary and, indeed, unwarranted. Changing the names of the old landmarks does not help the wayfarer to follow the new paths more easily. The latter chapters of the book deal with the comparative anatomy and physiology of this subject and give a full and critical account of all that is known about the cardiovascular system in the human foetus.

The make-up of the whole volume with its wealth of illustrations is something of a luxury to the wartime reviewer, and the authors are to be most heartily congratulated both on the completion of their outstanding researches, in spite of the encroachment of war activities, and on writing such a very clear account of them.

SURGERY OF THE UROGENITAL TRACT

Urological Surgery. By Austin Ingram Dodson, M.D., F.A.C.S. (Pp. 768; illustrated. 50s.) London: Henry Kimpton. 1944.

The main theme of this book, as its title suggests, is the surgery of the genito-urinary tract, but the diagnosis and pathology of urological diseases are also considered. To help him in dealing with the subsidiary subjects the author has obtained contributions from various experts. Despite this, *Urological Surgery* can be looked upon as being a book on operative surgery, and a book which is to a great degree the expression of its author's personal experience. He makes no claim for originality in the various operative techniques he describes, which have been chosen because he happens to have found them the most satisfactory in his work. Because he writes from personal experience, he writes convincingly and with admirable clarity, and it is the clarity of the descriptions which makes *Urological Surgery* a valuable addition to the large library of books on this subject which has already come from across the Atlantic. As is to be expected of such a work, it is profusely and splendidly illustrated. Miss Helen Lorraine's drawings of the various stages of an operation—for example, nephrectomy—make surgery appear so simple that a reader [illegible] er- [illegible] ous [illegible] level of ex [illegible] kidney and of [illegible] n that of the prosta [illegible]

The most [illegible] hole book are perhaps those [illegible] esection of the prostate, and, s [illegible] ng from personal experience, it wou [illegible] he does not make much use of this p [illegible] of relieving prostatic obstruction. It would [illegible] een more helpful if the author had given more [illegible] ation concerning the pre-operative and post-operative [illegible] tment of prostatectomy. But apart from minor defects this must be looked upon as a very successful book, and one that can be highly recommended to surgeons requiring an up-to-date guide to the surgery of the genito-urinary tract.

THE ANATOMIST OF MELANCHOLY

The Psychiatry of Robert Burton. By Bergen Evans in consultation with George J. Mohr, M.D. (Pp. 129. $2.00 or 13s. 6d.) New York: Columbia University Press; London: Oxford University Press. 1944.

In the speed and turmoil of modern life we have all too little time to study the wisdom of the ancients and yet there is still a lot to be learnt from them, obscured though that wisdom may be by outworn theories and superstitions. The modern physician and psychiatrist may indeed be excused for shrinking from the task of exploring the digressions and complexities of the early 17th century divine. But if they read this fascinating, short, and well-written study they may well be tempted to dip into the pages of the old melancholic to see how many of the most modern and in some respects the most startling theories in psychiatry have been thought of before by someone of the first intelligence. Such a discovery does much to convince the reader of the truth of such theories, for all good intellects are sure to catch glimpses of truth, distorted as these may be by contemporary beliefs and lack of relevant knowledge.

A great deal of the *Anatomy of Melancholy* is autobiographical, though the inclusion of symptoms of very diverse mental illness, especially of the psychoneuroses, prevents it from being a description of what we understand as melancholia. There is little extant about Robert Burton's life from outside sources, but the authors depict him as a man full of resentments, continual self-depreciation, cloaking discontent and aggressiveness, with mingled gaiety and depression, based on possibly hereditary taints, deprivation of love in childhood, and frustration especially in his sexual life, which were the three main causes of "melancholy" according to Burton himself. As is pointed out in the conclusion, Burton differed from his contemporaries, and his followers for two or even three hundred years, in realizing that these conditions were mainly of psychological rather than physical origin, that treatment involved a finding of the cause, was assisted by an emotional bond between patient and physician involving trust and respect by the former for the latter and kindness for the former by the latter. If only attention had been paid to him Pinel's reforms might have been antedated by 200 years. The *Anatomy* is not a medical textbook, its author was not a doctor, but he was a wise man with an understanding heart.

Members of the medical profession owe a debt to Mr. Bergen Evans and Dr. Mohr for affording them the best sort of relaxation—that of very pleasantly learning more about their own subject.

BOOKS FOR NURSES

Operative Surgery Described for Nurses. By O. Stanley Hillman, M.S., F.R.C.S. Second edition. (Pp. 263; illustrated. 7s. 6d.) London: Faber and Faber. 1944.

101 Clinical Demonstrations to Nurses. By Hamilton Bailey, F.R.C.S. (Pp. 136; illustrated. 10s. 6d., plus 6d. postage.) Edinburgh: E. and S. Livingstone. 1944.

Two books for the nurse's library have recently been published. The first—*Operative Surgery Described for Nurses,* by Stanley Hillman—is really a second edition, though as the first appeared as long ago as 1927 a good deal of fresh material has been added to cover the changes in surgical technique which have occurred in the interval. Thus we now find descriptions of operations upon the sympathetic nervous system and of such innovations as pinning the neck of the femur and cardio-omentopexy. The accounts of operations are brief but sufficiently detailed to enable the nurse to take an intelligent interest in the wide range of procedures which she is likely to see carried out in the operating theatre. There are some 50 line drawings to help her to visualize many technical details that might otherwise have been overlooked. It is not meant to be a practical guide for the theatre nurse and does not therefore contain lists of the instruments used, but it is a good introduction to operative surgery. Nurses can certainly turn to it with every confidence.

The second volume—*101 Clinical Demonstrations to Nurses*, by Hamilton Bailey—follows the lines of his similar book for medical students and consists of photographs of typical cases of well-known diseases with a brief description of the main features illustrated. The photographs, some of which are in colour, are well chosen and the reproduction is satisfactory. They cannot fail to convey to the nurse a clear impression of some of the common diseases met with in her work.

Notes on Books

The Nursery School Association of Great Britain has issued a pamphlet on *Planning the New Nursery Schools* (University of London Press, Malham House, Bickley, Kent; 2s. 6d.), which owes its origin to a special committee. It is full of useful information, but would have been even more valuable if the committee had included in its membership an experienced school medical officer or a physician with expert knowledge of the young child in health and disease.

Dr. DONALD PATERSON'S *Sick Children: Diagnosis and Treatment* (Cassell and Co., Ltd.; 16s.) has enlarged its shape and size for a fifth edition, and this indicates the completeness of the revision. New matter on penicillin, the rhesus factor, coeliac disease, and epidemic jaundice is included, and many other sections, including that on gastro-enteritis, have been revised.

Preparations and Appliances

A LIGHT "WELL-LEG" TRACTION SPLINT

Major A. C. BREWER, F.R.C.S., R.A.M.C., writes:

Battle casualties with fracture of the upper third of the femur are notoriously difficult to treat in the field. The present "Tobruk plaster splint" is by no means ideal, and a spica is not only difficult to apply without special apparatus but also unsatisfactory for travel. A wound which is high in the thigh makes it difficult to apply the fully ringed Thomas splint necessary to the "Tobruk" method. It is essential that the patient in a Tobruk plaster should reach a satisfactory base within ten days owing to the incomplete reduction and fixation of the fracture. To overcome these several disadvantages the following appliance is described.

Description.—Two half Thomas rings are joined together 8 in. from their axes into a simple rod. The material used is 1/4 in. round metal as in the Thomas splint. The rod is flattened and notched from a distance of 22 to 40 in. A crossbar fits on the primary rod and is secured in place by a simple wing-nut (see Fig. 1). The whole weighs 3¾ lb., as distinct from 5 lb. for the Thomas splint.

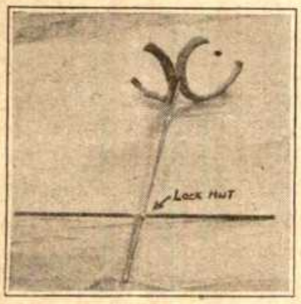


FIG. 1

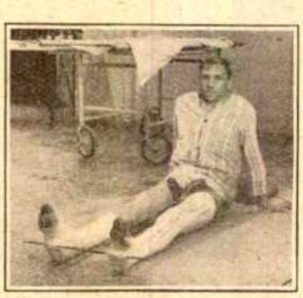

FIG. 2

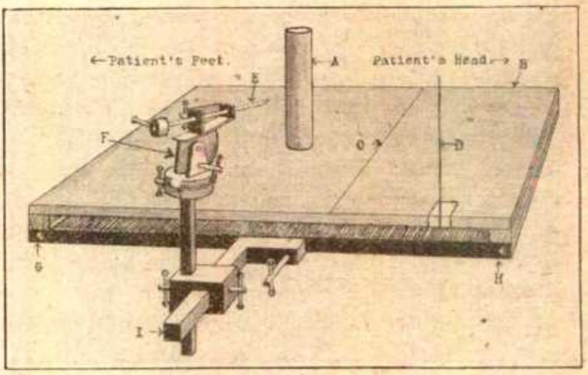
Method of Application.—The wound is dealt with on general principles. Both legs are then placed in padded plaster below the level of the knee. The feet are secured to the crossbar with plaster. Traction to reduce the fracture is applied to the crossbar, the "well leg" giving the required length. The lock-nut is screwed tight. Wool padding is applied around the thigh on the injured side and the plaster completed well up to the groin. The knee is slightly flexed by the assistant as the plaster hardens. A pillow is placed beneath the knee of the "well leg." Fig. 2 shows the appliance on a patient with a fracture of the mid-femoral shaft. It will be noted that the patient can easily sit up in the appliance. For transportation the splint crossbar is secured to the stretcher bar by means of a few plaster turns.

MECHANICAL JIG FOR ACCURATE INSERTION OF SMITH-PETERSEN NAILS

Mr. G. S. STORRS, F.R.C.S., surgeon to the Fracture Clinic, Bedford County Hospital, writes:

The apparatus clamps on to an orthopaedic table (Shropshire horse) and provides a perineal post (A), a buttock support (B), and a drawer which slides beneath B to enable antero-posterior films to be slid under the patient. The stainless-steel parts make up into the guide proper and can be fixed on to either side of the support. The head-piece (F) is adjustable in two planes, horizontal rotation and vertical tilt, and each adjustment is calibrated in degrees. A chisel-pointed guide wire sheath (E) slides through the head-piece. The head-piece can be raised or lowered, slid inwards or outwards along the projecting arm of the L-piece (I), or moved longitudinally by sliding the L-piece between the points G and H. Winged bolts will lock all the adjustments.



Technique.—The anaesthetized patient is put in position on the support, the fracture reduced, and the legs fixed to the traction bars of the table in abduction and internal rotation. Six dental needles (as skin markers) are inserted in a double row 1 in. apart parallel to the outer border of the shaft of the femur below the greater trochanter. Using two x-ray units antero-posterior and lateral films are taken. The line for insertion of the nail is marked on the films joining the centre of the head of the femur to the head of the best-situated dental needle. The angle of insertion is measured in both films, using the shadow of the transverse wire (C) in the antero-posterior film and of the vertical wire attachment (D) in the lateral film as base lines from which the angles are measured.

The stainless-steel parts are boiled and the head-piece is set to correspond with the two measured angles. The head-piece is then aimed at the selected dental needle and all locking bolts are tightened. A small incision is made and the guide-wire sheath is slid through the head-piece and pushed through the muscles and its point impacted into the cortical bone with a tap with a hammer and the sheath is locked in the head-piece, when it will be found to be perfectly rigid. A long 2.5 mm. guide-wire is inserted through the sheath and drilled into the bone. Antero-posterior and lateral films will show the wire in correct position in the bone, and the operation is completed in the usual manner.

It is claimed that the instrument is highly accurate, thanks to sound mechanical construction. It is in fact a precision tool. I am extremely grateful to a local engineering firm for the excellent construction of the apparatus to my designs and for presenting it to the Bedford County Hospital, where I have used it most successfully for the insertion of more than 24 nails.

British Schering Ltd. announce that after having been unobtainable for rather more than three years, "Uroselectan B," the original iodoxyl contrast medium in intravenous pyelography, is again in full supply. This product, formerly German-owned and made in Germany, is now British-owned and made in England.

TRINITROTOLUENE

Trinitrotoluene, which is the symmetrical trinitro derivative of toluene, was first made in the laboratory by the German chemist Hepp in 1880, and was first put to use as an explosive by the Germans in 1902. We can group explosive charges broadly into three divisions: initiators or detonators, of which the two most important are mercury fulminate and lead azide; intermediates, for which tetryl is usually used; and the main explosive charge, for which, until recently, a T.N.T. mixture was always employed. Contact with T.N.T. causes yellow discoloration of the skin, nails, and hair; its vapour and dust irritate the mucous membranes and bring on sneezing, sore throat, and irritable cough. Dermatoses include a superficial erythema which may become thickened, papules, and itchy eczema (especially in uncovered parts of the body); vesicles may sometimes be formed. Skin rashes are commoner in women than in men. Gastro-intestinal symptoms include pain, nausea, vomiting, loss of appetite, and diarrhoea; tenderness below the right costal margin has been thought to indicate involvement of the liver. The most serious sequels of T.N.T. poisoning are jaundice and toxic hepatitis, which may end in yellow atrophy of the liver; they have a mortality rate of 25 to 30%. The most conspicuous findings in T.N.T. anaemia are reduction of the red blood cells and of the haemoglobin, which may be associated with fragmentation of the red blood cell, stippled cells, reticulocytosis, and eosinophilia. Relative lymphocytosis appears to be the most common change of the white blood cell picture. Cyanosis of the lips and ears, frequent in cold weather, may be due in part to the formation of a chromogenic pigment derived from T.N.T. and in part to the formation of methaemoglobin and sulphaemoglobin. Effects on the nervous system largely result from anoxia and consist of dizziness, headache, fatigue, and sleepiness, but in severe cases may include delirium, convulsions, and coma. Signs of peripheral neuritis and pain in certain muscle groups are not infrequent. Vasomotor irregularities, palpitation, oppression in the chest, and bradycardia have been reported, as well as urinary symptoms such as lumbar pain, urgency of micturition, albumin, and casts. In women menstrual irregularities occur.

At first T.N.T. was thought to be a non-toxic substance, and Prosser White[1] showed that dinitrobenzene was more toxic to animals; but in the last war the first fatal case occurred as early as February, 1915. So many workers were poisoned that on January 1, 1915, toxic jaundice was made a notifiable disease; as a result 181 cases with 52 deaths were notified in 1916 and 189 cases with 44 deaths in 1917; the greater knowledge of the danger and the introduction of preventive measures reduced the notifications in 1918 to 34 cases with 10 deaths. In the same period there were 15 fatal cases of aplastic anaemia. Similar observations were made in Germany and the U.S.A. Koelsch[2] concluded that pure, recrystallized T.N.T. does not possess the toxic properties of the crude material, that serious toxic effects from fairly pure material are exceptional, and that the degree of contamination was the decisive toxicological factor. Voegtlin and his co-workers in the field of experimental pathology[3] observed that susceptibility varied in different animals, guinea-pigs and rabbits being less sensitive than cats and dogs. In England the Medical Research Council promoted much work, as a result of which Moore[4] thought that the usual route of absorption was through the skin; Webster[5] developed a valuable chemical test for demonstrating the presence of T.N.T. derivatives in the urine, and Panton[6] showed that toxic jaundice and anaemia appeared to be separate pathological states. Anaemia might occur without jaundice, while only 17% of the jaundiced patients became anaemic.

During the present war only 99 cases of toxic jaundice, of which 23 were fatal, had been notified up to the end of 1943, while nine cases of toxic anaemia had occurred before February, 1942. It seems certain that this smaller incidence is not entirely due to preventive measures, although these have been most efficiently carried out. The lower incidence of toxic manifestations after the installation of exhaust ventilation confirms the view of Von Oettingen[7] that the principal portal of entry is through the lungs and not the skin, as was thought by Moore. Our relative freedom from serious trouble in the present war may be due to the improved manufacturing methods of to-day, which produce a T.N.T. practically free from isomers, whereas in the last war these were present in considerable quantities. Improved diet may also have played a part. Himsworth and Glynn[8] showed that rats treated with α-T.N.T. and fed on a high-fat diet developed necrosis of the liver; while ill effects were slight or absent in animals fed on a high-carbohydrate or a high-protein diet. Himsworth[9] has suggested that T.N.T. combines with amino-acids, forming a combination which cannot be used by the body; thus a state of conditioned amino-acid deficiency may arise, and in such a state the liver may be damaged. Von Oettingen[7] was unable to injure the liver in experimental animals. Different animals metabolize T.N.T. through different chemical derivatives, and he suggests that some of these amino derivatives produced in the organism may have a more injurious effect on the liver than others. The occurrence of toxic hepatitis in T.N.T. workers might be explained on a basis of a greater production of the more toxic metabolites. Channon, Mills, and Williams[10] attempted to obtain information on the fate of T.N.T. in the body by means of experiments on rabbits. The presence in the urine of animals fed on α-T.N.T. of 2 : 6 dinitro-4-hydroxylaminotoluene, 2 : 6 dinitro-4-aminotoluene, and 2 : 4 dinitro-6-aminotoluene (which may be estimated accurately by spectrophotometric methods[7]) points to some reduction mechanism. T.N.T. may also be oxidized: experiments with trinitrobenzyl alcohol in attempts to establish the origin of the red pigment indicate the probable existence of such a mechanism, since only α-T.N.T. and 2 : 4 : 6 : trinitrobenzyl alcohol would cause excretion of red pigment. Present knowledge of detoxication mechanisms suggests that the glucuronides of T.N.T. urine must arise from T.N.T. oxidation products. they are probably trinitrobenzyl glucuronide, or dinitroaminobenzyl glucuronide, or a mixture of both. The hydroxylamine derivative provides an example of the making of a more toxic product in a detoxication mechanism, and it is a powerful former of methaemoglobin *in vitro*. Since the first stage in the biological reduction of T.N.T. is the formation of dinitrohydroxylaminotoluene, there is produced a very reactive compound which may be harmful to the blood and may poison some of the enzyme systems. The hydroxylamine can be detoxicated by conversion into the relatively non-toxic dinitroaminotoluenes, and its poisonous effects will depend on the rate at which this conversion occurs. Although the conversion takes place *in vivo* it is by no means complete, for the hydroxylamino and the amino compounds are excreted in the urine in roughly similar amounts. The formation of dinitrohydroxylaminotoluene may therefore partly explain the toxic action of T.N.T. Doses of T.N.T. up to 150 mg./kg. are eliminated in 24 hours; larger doses require up to 48 hours; 47% of the T.N.T. administered is excreted as glucuronides and 30% as aromatic amino compounds. The aromatic amino compounds include not only dinitroaminotoluenes but possibly dinitroaminobenzyl alcohol conjugated with glucuronic acid. Trinitrobenzylglucuronide is also a likely constituent. The red 2:2′:6:6′-tetranitro-4′:4-azoxytoluene isolated by previous workers is not a metabolic product; it is absent from freshly voided urine and is formed from dinitrohydroxylaminotoluene during the extraction procedures. Rimington and Goldblatt[1] have shown that workers handling aromatic nitro and amido compounds have a greatly increased urinary coproporphyrin excretion, and this change is also found in T.N.T. workers.

Little clinical work has been possible on T.N.T. poisoning during the present war, but during the Russo-Finnish war Noro[12] observed that in Finnish T.N.T. workers reticulocytosis was not very great during the period of actual exposure, but that it became more evident when the worker left contact with T.N.T.; this suggests that reticulocytosis was a reparative phenomenon which is to some extent inhibited by T.N.T. In order to establish the early effects of exposure to T.N.T. Higgins, O'Brien, Stewart, and Witts[13] examined a number of Oxford students who volunteered to work in a filling factory during their vacation. The chief subjective complaints were nausea with variable loss of appetite, diffuse abdominal pain, vomiting and diarrhoea, fatigue, and irritation of nose and throat. The symptoms came on after an initial period when there was an increased sense of well-being accompanied by a voracious appetite. There was evidence of haemolysis in over 85% of the students, with a fall in haemoglobin, red cell, and haematocrit readings. There were also an increase in reticulocytes, bilirubinaemia with urobilinuria, and a marked erythroblastic response in the marrow. As Noro found, the reticulocyte response was not maximal until a few days after exposure had ceased. This suggests that T.N.T., in addition to a destructive action on the circulating red cells, also affects the bone marrow.

GAMMA GLOBULIN

The story of how human blood has been harnessed to the war effort will prove to be among the most fascinating tales of our generation. In the early days of the war blood banks and improved methods for the preservation of whole blood were successfully established. Then, with the emphasis on shock, harvesting of the plasma proteins became important, and large-scale methods of freezing and drying plasma and serum were evolved. Meanwhile in America before the war, but accelerated by the war, methods for the fractionation of the plasma proteins were being steadily developed in the department of physical chemistry at Harvard under the direction of Prof. E. J. Cohn. The methods themselves were revolutionary in their utilization of new physical and chemical processes: high-speed centrifugation, electrophoresis, diffusion, viscosity, and precipitation at iso-electric charges have all been used for the separation of different protein fractions with the least possible damage to the constituents. The story has lately been summarized by Cohn[1] himself, while various chemical, immunological, and clinical aspects are described in a special symposium[2] on the subject.

Plasma has been conveniently divided into five fractions: I is largely fibrinogen; II and III contain gamma globulin, the iso-haemagglutinins and Rh antibodies, and prothrombin; IV is mostly alpha and beta globulin; and V is albumin, which constitutes nearly 60% of the total proteins. Indeed, the fractionation of plasma on a large scale was first undertaken in order to obtain the albumin in concentrated form for the treatment of shock. Having a small, fairly regular molecule, albumin contributes 80% of the osmotic pressure of plasma proteins and can be prepared as an iso-viscous 25% solution which osmotically is four times as concentrated as plasma. Besides its value in shock, concentrated albumin may be used in the treatment of hypoproteinaemia, oedema, and (because of its low salt content) as a diuretic. Of the other proteins thrombin supplied in a matrix of fibrin, called fibrin foam, has been used as a haemostatic in neurosurgery and in controlling bleeding from oozing surfaces and in haemophilia. Being composed entirely of human proteins, fibrin foam is absorbed with the minimum of reaction. Again, fibrinogen has been worked up like a plastic to prepare fibrin films which, with the properties of a rubbery sheet,

have been used as dural substitutes and in the prevention of meningo-cerebral adhesions.

Probably the most important derivative of plasma will be the gamma globulin, which contains a large part of the natural antibodies of the blood. Gamma globulin constitutes about 11% of the plasma proteins, and the greater part of this globulin has now been fractionated in practically pure form from the combined II + III fraction. The concentration of antibody as judged by the estimation of the diphtheria and streptococcus antitoxin and influenza virus A antibody is 15 to 20 times that of the natural pooled plasma, and its content of certain antibodies equals or exceeds that of convalescent serum. There has been remarkable uniformity in the potency of different pools from various regions of America. Gamma globulin has already been used on a large scale for the prevention and attenuation of measles in familial contacts and in institutions; analyses indicate that a dose of 2.0 to 2.5 c.cm. will protect 80% of young, susceptible, and intimately exposed children, with marked attenuation in the remainder. Where attenuation only is desired the recommended dosage is around 0.5 c.cm. In other words, results equal to those obtainable with convalescent measles serum have been achieved with one-quarter to one-half the dosage of that rather rare commodity. Although the gamma globulin now issued cannot be used intravenously, progress has been made with the removal of the depressor substance which precludes intravenous therapy, and it seems likely that such a preparation will be useful for the treatment of early cases of measles and other infections. Meanwhile there are other obvious fields for its prophylactic use. Thus Stokes and Neefe[3] tried it in summer camps for boys and girls where a widespread epidemic of infectious hepatitis was occurring, with reasonable hopes of success since the incubation period is long and the infecting agent is presumably present in the blood during the pre-icteric stage of the disease. Among 29 boys injected with doses equal to 0.15 c.cm. per kilo of body weight, 4 (13.3%) developed hepatitis without jaundice, whereas among 130 controls 90 (69%) became infected, and two-thirds of them had jaundice. Of the inoculated girls 3 out of 16 (18.7%) developed hepatitis with scleral jaundice only, while 82 of 116 controls (70%) became infected. The better results obtained among the boys were attributed to the injections being given earlier in the incubation period in that group. The authors remarked on the apparent absence of the "hepatitis agent" in gamma globulin used for large-scale prophylaxis of measles, and this finding, if corroborated, may be another argument for the fractionation of human plasma. Further clinical experience and improvements in the methods of assay will show whether gamma globulin will be useful for the prophylaxis of other virus and bacterial infections—e.g., chicken-pox, mumps, pertussis. Some of the natural antibodies seem to be concentrated in other fractions. However, the proven value of this derivative of human blood will act as an incentive to blood donors to carry on into civilian life the magnificent work they have done in response to the demands of war. It is to be hoped that our chemists and biophysicists will soon be given opportunities to develop this new field.

FOOD CONTROL

The long controversy over preservatives in food ended with the passing of the Public Health (Preservatives, etc., in Food) Regulations of 1925. Many experts had advocated that the use of particular preservatives should be forbidden, but the Ministry of Health adopted in these regulations the much sounder plan that all preservatives (except the common types like sugar or vinegar) should be prohibited except those specifically permitted for indicated foods and only in amounts which must not be exceeded. It was never suggested that the last word had been said, but the principle was established that nothing might be added unless specifically authorized and under defined conditions as to the preservative to use, its quantity, and the food to be preserved. Under war conditions the conserving of food supplies became urgent, and the central authorities concerned—i.e., the Ministries of Health and of Food—had to face the question of relaxing certain requirements if it could be shown that it favoured the conserving of more food and was not harmful to the consumer. Obviously such decisions are not easy, involve the balancing of various opposing factors, and demand an intimate knowledge of the conditions of food preparation and preservation. This need accounts for the rather bewildering number of Orders that have been issued—some allowing certain relaxations, others cancelling relaxations previously permitted. One of the latest is Regulation 60 CAA of the Defence (General) Regulations, 1939, and is a good illustration of the way in which preservatives are being controlled. It allows oranges to be imported in wrappers treated with diphenyl; meat and dehydrated vegetables may contain sulphur dioxide, and margarine and bacon borax; jam may contain more sulphur dioxide than in the original Regulations—i.e., up to 100 parts per million. Two sections of the Order relax certain requirements of the Public Health (Condensed Milk) Regulations, 1923, and there are requirements as to preserved eggs and their markings.

While the changes are not in themselves of much importance, this new Regulation illustrates very well the complexities of food production, preservation, and sale under modern conditions. These various Orders will no doubt be revoked or amended when the war is over, but the need for food control will still remain. Many people clamour for the removal of control and for unrestricted freedom. But food conditions are so complicated that if all controls were removed the state of affairs would be chaotic. The Ministry of Food, being wise enough to obtain and use expert advice, has done a sound bit of work not only in feeding the people but in improving the qualitative dietary of all. Some of this work, such as school meals, school milk, special foods for babies and expectant mothers, should continue; there is also a need for scientific control over food production and conservation. In these fields we now have a volume of accurate knowledge, which, however, needs scientific application and some measure of control.

A FLUORESCENT GUIDE TO LOCAL CIRCULATION

The diagnosis and still more the prognosis of peripheral vascular disease is a complicated matter which needs the accurate plotting of skin temperatures, oscillometric determinations, and often arteriography after injection of thorotrast or other x-ray-opaque solution, and the effects of blockage of the sympathetic innervation or of intermittent venous occlusion. A relatively simple method which gives a direct insight into the nutrition of the tissues is therefore welcome, especially when it has been thoroughly tested in over 1,000 patients without untoward reactions. A 5%

---

[3] *J. Amer. med. Ass.*, 1945, **127**, 144.

fluorescein solution is injected intravenously, and its arrival in the tissues under examination demonstrated by its fluorescence under ultra-violet rays. Fluorescein absorbs the invisible ultra-violet and converts it instantaneously into a visible yellow-green light; the method thus requires only a dark room and a mercury-vapour lamp with an appropriate filter to give an ultra-violet beam of wave-length 3,600 Å.U., at which fluorescein shows its maximum fluorescence. The lamp can be directed on to any part of the patient, and the fluorescence of suspected areas of deficient circulation can be rapidly compared with the normal. In the common type of diabetic gangrene, for example, there is a marked decrease in fluorescence of both limbs and an entirely non-fluorescent distal gangrenous area, indicating that amputation should be done at a high level; but in a second type the general fluorescence of the limb is almost normal, and around the area of gangrene there is a zone of hyperfluorescence, indicating a vascular demarcation reaction of the surrounding tissue which will prevent further spread of the gangrene, so that amputation is not required. The hyperfluorescence is mainly due to increased capillary permeability, and it is thus possible to distinguish the reddish-blue discoloration of a foot due to commencing inflammation (incipient gangrene) from that due to stasis —the former being *hyper*fluorescent, and the latter *hypo*fluorescent. In acute embolism the test permits the exact establishment of the level of blood supply in the skin and how far a procaine block of the sympathetic chain will improve the collateral circulation. In two of Lange and Boyd's cases[1] they were able to show that the embolus, though it had caused coldness and blanching, had not led to complete vascular occlusion, since the tips of all toes were fluorescent; and the subsequent clinical course bore out their contention that gangrene would not occur. The test is valuable in establishing an immediate prognosis of frostbite, and it will show in chronic ulcers whether skin grafts will "take."[2] For studies of capillary permeability and for physiological rather than pathological investigations Lange and Krewer[3] have introduced a refinement by which the amount of fluorescence can be objectively determined, and their "dermofluorometer" is essential in the examination of coloured people, since skin pigmentation interferes with visual observation of the fluorescence.

CLINICAL EFFECTS OF VIBRATING TOOLS

Pneumatic tools were first used in the French mines as early as 1839; now they are used extensively in many industries: in shipbuilding for riveting and caulking, in foundries for fettling, in road-making and stone quarries, and in scaling boilers. The to-and-fro motion of these tools can also be converted to a rotary one, and they can be used as drills. Similar tools are made in which the power is generated by electric or other kinds of motor instead of by compressed air. Vibrating tools have been reported as giving rise to several clinical syndromes—white fingers; arthritis of wrist, elbows, and shoulders; the formation of areas of decalcification in the bones of the carpus; and injuries of the palmar aponeurosis and the ulnar nerve. Arthritis has mostly been found in miners in the Northern French, Belgian, Rhineland, and Westphalian mines,[4 5] where a heavy tool is used. In England pneumatic tools are rarely used in the mines, but Hunter, McLaughlin, and Perry[6] in a recent survey found little evidence of arthritis in riveters, caulkers, or fettlers, though they found six cases of arthritis of elbow among twelve scalers. These figures are small, and no conclusions should be drawn from them until more scalers have been examined. Dupuytren's contracture and ulnar paresis can undoubtedly result from the pressure of these tools on the palm of the hand, but such occurrences are rare. Large bruises are commonly found on the back of the hands of riveters who work on the under side of ships; they are caused by the hand being constantly knocked against the knee when the tool is used in an inverted position. Brailsford[7] found on *x*-ray examination small areas of decalcification in the bones of the carpus of pneumatic-tool workers, and confirmation of this has been given by McLaren.[8] Such areas are probably due to repeated trauma and not to the vibration of the vibrating tools. They certainly occur in men who have never used these tools; but an investigation is needed to find out how frequent are these decalcified areas in the carpus in the general population. Hunter, McLaughlin, and Perry[6] found them most frequently in "holders up," 18 out of 28; whereas in the users of vibrating tools they occurred in 45 out of 78 riveters, 18 of 36 caulkers, and 51 of 108 fettlers.

The most important of the syndromes from which these workers suffer is a vascular disturbance which produces a local anaemia in the fingers, making them stiff and awkward; and in severe cases the symptoms may prevent the men from working or cause them to seek other employment. Maria Seyring[9] in Germany reported that 92 out of 189 fettlers complained of white fingers; 61% of the men who had been on the work for more than 10 years had the syndrome. It occurs mostly in the left hand in right-handed workers and in the right hand in left-handed workers. The hand which holds the tool bears the brunt of the vibration, and Hunt[10] suggested that this vibration was the fundamental cause of the trouble. He emphasized that the body and handle of the tool vibrate less than the striking end. Cold is undoubtedly a precipitating factor, but the striking end of the tool is always hot from friction, and the cold air escapes through the exhaust, which is directed away from the man's hand. Hunter, McLaughlin, and Perry[6] found the condition in 74% of men who used tools with a stroke speed between 2,000 and 3,000 a minute, and they thought this was a critical frequency; but they pointed out that these men also worked with cold metal—they were caulkers and fettlers. Riveters, who use tools with a vibration speed under 2,000, drive red-hot rivets; the syndrome was present in 23 out of 43 cases. The symptoms are not accompanied by constitutional changes which would prevent a man attending at his place of work. There is, nevertheless, a disability which will stop him working until the circulation returns to his hand; and when the syndrome of white fingers has been established it tends to recur on exposure to cold for some years after the worker has given up the use of vibrating tools. Junghans[11] demonstrated arteriovenous thrombosis histologically, and Barker and Hines[12] by means of thorotrast have shown obstruction to the ulnar artery; but only two cases[13 14] of gangrene of the fingers are mentioned in the literature.

The Moynihan Lecture for 1944 (delayed on account of the exigencies of military service) will be given on Thursday, June 7, at 3 p.m. in the Riley Smith Hall of the University Union, Leeds, by Brig. J. A. MacFarlane, M.B.Toronto, F.R.C.S. (Hon.), F.R.C.S.Ed., Consulting Surgeon, Canadian Army Overseas. Subject: "The Management and Results of War Wounds of the Abdomen, 1944." Members of the medical profession are cordially invited to be present.

THE EPIDEMIC OUTLOOK IN EUROPE*

BY

KNUD STOWMAN, M.D.

Chief of the Epidemiological Information Service of U.N.R.R.A.

During the more than five years of destruction and privation, accompanied by forcible or voluntary displacement of a large fraction of a populous continent's inhabitants, there has been no pandemic of first magnitude. Gratifying though this is, the fact must not be taken to mean that the epidemic situation is as satisfactory as it was before the war, nor as indicating a favourable outlook for the first years of transition to stable peace. The absence of real disasters may be traced to the low endemic level of most diseases during the years preceding the war, in conjunction with the advance of preventive medicine and the application of its principles on a large scale. On the other hand, caution against over-optimism is dictated by the disastrous aftermath of World War I.

During the four years of World War I Europe witnessed a rise in the endemic level of infectious diseases, and there were various pestilential outbreaks, such as that of cholera in Galicia in 1915, which caused over 17,000 deaths. A devastating typhus epidemic broke out in Serbia in 1915, causing 150,000 deaths in six months, and there were severe typhus epidemics in Egypt. Moreover, typhus caused several hundred thousand deaths in Rumania during the winter of 1917–18. There were extensive smallpox epidemics in various countries. Nevertheless, it was after the cessation of hostilities and following the disintegration of established government over wide areas that typhus, relapsing fever, cholera, malaria, dysentery, and typhoid fever swept across Eastern Europe, leaving millions of victims, and made serious inroads also in Southern and Central Europe. Whether directly due to conditions of war or not, it was at the time of the Armistice that the influenza pandemic struck, causing in less than half a year twenty million deaths throughout the world.

With World War II entering its final stage, civil administration is now in a fluid state in many areas and refugee movements are gathering momentum. These conditions, propitious to the propagation of epidemics, are likely to grow worse during the current year. They will further complicate the return to their native countries of millions of prisoners of war, shanghaied labourers, forcibly displaced people, and other uprooted men, women, and children, in themselves constituting grave potentialities so far as epidemics are concerned.

Appreciation of the problems at hand may be based on: (1) the trend of epidemic diseases in recent years in areas for which fairly accurate epidemiological data are available; (2) fragmentary information regarding the areas where no precise records of recent date exist; and (3) various estimates of displaced persons. The last-mentioned problem, which has other angles than the epidemiological, will not be dealt with in this summary.

Recent Trend of Epidemic Diseases

It may be said at once that among the five pestilential diseases covered by the International Sanitary Conventions only louse-borne typhus presents an immediate and grave danger to Europe. *Cholera*, which is a serious problem in Asia, has not appeared within recent years west of India and Afghanistan. *Yellow fever* seems hardly to have spread during the war, and has not been observed north of the North African desert belt. It should be added, moreover, that had no precautions been taken, the extension of these diseases would probably have been different.

Plague.—So far as we know, plague has not been introduced into any European port during the war. Nevertheless, this may happen at any time, as it did after World War I, because several large ports in North Africa and the Near East have become infected. The most important near-by foci are in the Suez Canal zone and at Dakar. Although they are quiescent at present on account of the season, these foci may flare up again. Meanwhile infection has spread to other ports, such as Haifa and Jaffa in Palestine, Ferryville in Tunis, Algiers and Oran in Algeria. The old plague centres in Morocco, especially at Casablanca, and in the Azores have also shown renewed activity in recent years. The outbreak in the Suez Canal zone from Nov., 1943, to Sept., 1944, was the worst on record, 712 cases being reported, as against 359 in 1917. There were over 500 plague cases at Dakar in 1944, which is equal to the number notified in 1931, the worst year since 1920.

Smallpox.—Europe has remained practically free from smallpox during the war except for the 1944 outbreak in Sicily and Southern Italy, and an extension of the Near East epidemic into European Turkey and the neighbouring parts of Greece. The latter epidemic, which was of the classical type, has now come to an end. The Italian epidemic, the first case of which appeared in March, 1944, has centred at Palermo and at Naples and the vicinity. Although there have been some 1,500 cases all told, the epidemic is apparently not of prime importance, because all cases have been of the mild type. Only six deaths were reported, all among debilitated children. In this connexion it may be of interest that mild-type smallpox seems to have gained ground in French North Africa, while the classical type still prevails in the Near East. In the Iberian Peninsula, where smallpox was widespread during the early years of the war, there are now only sporadic cases of variola minor. The most encouraging element in the whole epidemic situation is that there were only 3 cases of smallpox in 1944 (7 cases in 1943) among the more than 200 million inhabitants of Continental Europe outside the Soviet Union and the Mediterranean peninsular areas. In 1919 there were nearly 50,000 cases of smallpox in this area.

Typhus.—Typhus presents a far greater danger than smallpox. In certain areas severe epidemics are already under way, and in much larger areas the danger is potential because for several years there has been an insidious spread of sporadic infection throughout Central Europe. It should also be remembered that North Africa and the Near East are just emerging from an epidemic wave extending from Morocco to Iran, which has been among the worst on record in several of the countries. The Soviet Union was the principal sufferer from typhus after World War I, but has apparently succeeded in keeping this disease under close control during the present conflict. The publication of records was discontinued, however, a couple of years before the outbreak of the war. In Poland typhus is known to have been on the increase during the German occupation, but numerical indications are not available for the last four years.

There are three main epidemic foci of typhus in South-Eastern Europe: the Rumanian, with centre in Bessarabia and Eastern Moldavia; the Sub-Carpathian, with centre in Sub-Carpathian Ruthenia and extending into North-Eastern Hungary; the Croatian, with centre in Bosnia and probably extending into Serbia. All of these foci were in rapid evolution in the spring of last year, and there was a serious epidemic in Croatia and Bosnia, extending late into the summer. Information for recent winter months is not available for the Sub-Carpathian area. An epidemic reminiscent of the World War I disaster has broken out in Rumania. Unofficial information gives 30,000 cases in Moldavia alone, and the epidemic is likely to increase up to April or May. So far, this is undoubtedly the most serious epidemic outburst of any disease during the war. In recent years the epidemic level has been rising also in Bulgaria and Greece, and typhus was epidemic in Turkey in 1943. On the other hand, the typhus epidemic which visited Spain in 1941 and 1942, causing over 11,000 cases, has now been reduced to an endemic level. The outbreak in and around Naples during the winter of 1943–4 (somewhat over 1,000 cases all told) was brought under control in the course of a few months, and at present there is hardly any typhus in Italy. In Germany, where typhus was formerly unknown, there were over 5,000 cases in 1943, mostly among foreign workers. The cases were spread over the entire area of the Reich as far west as the Rhineland. Information for recent months is not available, but present conditions obviously favour the spread of infection. The typhus-free area of the European continent now consists only of the three Scandinavian countries, Finland, Switzerland, and, aside from relatively rare sporadic cases, the Netherlands, Belgium, and France.

With the exception of an outbreak in Tunis in March and April, 1944, and the tick-borne cases in Spain, *relapsing fever*, which followed on the great typhus epidemics of 1919–21, has not been heard from during the present war.

The above-mentioned diseases specially dealt with by the Sanitary Conventions—namely, cholera, yellow fever, plague, smallpox, and typhus—are international quarantine diseases not merely because they are the most dangerous, but also because they are of limited geographical extension and their introduction into uninfected areas is consequently feared. Various other epidemic diseases, such as typhoid fever, diphtheria, scarlet fever, and influenza, are numerically more important in Europe, but they are normally endemic in all countries. International transmission thus becomes of importance only when they develop particularly virulent strains locally or attain an unusually high incidence.

Scarlet Fever.—Scarlet fever has spread almost as much as diphtheria, and with few exceptions its incidence is from two to five times the pre-war level. Nevertheless, there has been no explosive epidemic comparable to the diphtheria outbreaks in the Netherlands and Norway. There seems to have been no change in type or gravity of the disease. A heavy increase of measles has also been noted, especially during the earlier years of the war.

Influenza.—The only important epidemic disease which seems to have remained unaffected by the war is influenza. The usual winter waves have come and passed, the most recent reaching its peak during the early part of the winter of 1943–4. In spite of abnormal living conditions none of them attained the gravity of the three or four most serious inter-war epidemics. The change from influenza B to influenza A reported to have taken place in England between the 1942–3 outbreak and that of 1943–4 does not seem to have had any visible effect upon the mortality. Nevertheless, the danger of major epidemics cannot be entirely disregarded.

Endemic Diseases

In addition to the epidemic perils, the increasing incidence of endemic diseases, such as malaria, syphilis, and tuberculosis, must be carefully considered. *Malaria* is the leading cause of morbidity large part of the Mediterranean basin, and it is reported to med epidemic proportions in Greece during the last couple areas of high endemicity in the Balkans and in Italy s time returned to their lamentable pre-control must be counted on, especially in view *lciparum* infection predominates in tries, while further north *vivax* extend northward into

Reports of Societies

THE VITAMIN B COMPLEX

A joint conference of the Biochemical Society and Nutrition Society was held on April 28 at the London School of Hygiene and Tropical Medicine. Prof. R. A. PETERS, who presided during the morning session, opened the proceedings with an expression of sympathy for the starving people in North Holland, and of the desire of all nutrition workers to give active help. After referring to the pioneer work of Eijkman and other Dutch investigators, Prof. Peters spoke of his own early work and that of Dr. Harriette Chick, of the Lister Institute, in the first steps towards the differentiation of the various members of the vitamin B complex. He emphasized that the labels vitamin B_1, B_2, B_3, etc., were originally adopted for the immediate convenience of the workers concerned. If the terminology had been changed in the light of additional knowledge it must not be implied that the original conclusions were necessarily at fault.

Dr. L. J. HARRIS, with Dr. E. KODICEK, in an introductory survey of the vitamin B complex, showed how, nearly 20 years ago, it had been found, mainly in work with rats and pigeons, that when sources of the original "water-soluble B" were heated until their antineuritic properties were lost certain other nutritive properties remained. This led to the postulation of two vitamins. The heat-labile factor was described as vitamin B_1, and has since been isolated and synthesized in the form of aneurin. The second factor was termed vitamin B_2. It soon found that riboflavin, a yellow fluorescent substance from milk whey, and now known to be very widely living tissues, could restore growth in animals ficient in vitamin B_2. The responses were it became obvious that other factors tment of concentrates of vitaorbents some factors were to the filtrate. The plex was now *-stable,* vin, In 1934, however, it attracted interest from a different direction, when Warburg and Christian showed that nicotinamide was present in the coenzyme involved in the oxidation of hexosemonophosphate. Later Euler and his colleagues also obtained nicotinamide from cozymase, the coenzyme of alcoholic fermentation. It was left to Elvehjem to prove that nicotinamide cured the disease " black tongue " in dogs, which was analogous to pellagra in man. As with aneurin, research had revealed that nicotinamide intervened in metabolism at numerous points. It was concerned not only with carbohydrate but with protein metabolism, its general role being that of an intermediary capable of receiving hydrogen from various substrates activated by different enzymes and of passing it on to other substrates activated by other enzymes. Riboflavin was isolated from yeast by Warburg and Christian as a conjugated flavoprotein, which was called " yellow enzyme." Soon afterwards Kuhn, György, and Wagner-Jauregg obtained riboflavin from milk, and found that it had growth-promoting action in animals. Numerous flavoproteins had been described, and might be regarded as a special class of dehydrogenases. One of their numerous roles was to act as " diaphorases " in facilitating the oxidation and reduction of coenzymes containing nicotinamide. Less was known of the part played by other B_2 vitamins in enzyme systems, but pyridoxine was concerned in the decarboxylation of amino-acids.

Less Familiar Members

Dr. F. A. **ROBINSON** followed with an account of the recently characterized members of the vitamin B_2 complex. Pyridoxine, and the related bacterial agents pyridoxal and pyridoxamine, pantothenic acid, *p*-aminobenzoic acid, the anti-anaemia factors α and β pyracin, xanthopterin, the monkey vitamin M, and several other less familiar factors were mentioned. It seemed probable that the distinction of the better-known vitamins—aneurin, riboflavin, and nicotinamide—from the lesser-known members of the vitamin B complex was more real than might be supposed. Present evidence suggested that the animals only showed specific deficiency symptoms in the absence of the first three vitamins. The others might be required only for the well-being of the intestinal flora. Inositol and choline, apart from their effect on bacteria, were known, however, to help in preventing an undue accumulation of fat in the liver, and might therefore be considered as a separate lipotrophic group.

Dr. B. C. J. G. **KNIGHT**, discussing growth factors and growth inhibitors for micro-organisms, emphasized that the wide distribution in nature of similar enzymatic systems supported the conception of the fundamental unity of all biochemistry, whether studied in yeasts, bacteria, fungi, protozoa, or higher animals. Thus it was now almost a commonplace occurrence that nutrients first found to be necessary for bacteria should later prove to be essential for higher animals, or vice versa. Usually when an organism did not need a certain substance as a nutrient the reason lay in its ability to synthesize this substance for itself. In building coenzymes I and II different micro-organisms were known which required ammonia, nicotinic acid, nicotinamide, or nicotinic riboside as a starting-point. The study of the action of growth inhibitors had furnished information of great biochemical interest. Woods discovered that the bacteriostatic action of sulphonamides was prevented by *p*-aminobenzoic acid, which was a naturally occurring metabolite. *P*-aminobenzoic acid was soon found to be a growth factor for several bacteria. Fildes concluded that growth inhibitors were substances which resembled essential metabolites sufficiently to compete with them in enzyme systems or in other ways, but which could not fill the specific role of the metabolite. The bacteriostatic action of the sulphonamides must therefore be ascribed to their interference in the metabolism of the chemically similar *p*-aminobenzoic acid. Many other examples of inhibition were now known; thus riboflavin was inhibited in its action by iso-riboflavin and mepacrine, aneurin by the related pyrithiamin.

Dr. F. **BERGEL** recalled that Williams in America had recently designated certain vitamins, including aneurin, riboflavin, and nicotinamide, as " major " vitamins, whereas the lesser-known B vitamins were termed " minor." The division was at least in line with the production of more characteristic and specific lesions in the absence of the " major " vitamins.

Synthesis and the Intestines

Dr. B. S. **PLATT** described the brewing of Kaffir beer, which in his belief had great value in maintaining the health of the natives. Clear beer, as brewed in this country, contained no aneurin, though it was a good source of riboflavin. The unclarified native beer was rich in all members of the vitamin B complex. In the West Indies the steps taken to improve nutrition included the provision of 80% extraction flour " ennobled " with 3% of food yeast. More information on the synthesis of the vitamin B complex in the human intestines was urgently required. It was important to realize that the products of bacteria were greatly influenced by the substrate. Thus bacteria which produced toxins, indol, or proteolytic enzymes when cultured upon proteins produced only lactic acid when cultured upon carbohydrates. After a heavy meal rich in carbohydrate the alcohol content of the blood, so far as could be judged from methods of estimation at present available, might sometimes be increased to levels consistent with advanced inebriation, suggesting that alcohol might possibly be produced in the intestines.

Dr. **LUCY WILLS**, speaking of her work on the vitamin B_2 complex and anaemia, said nutritional macrocytic anaemia was an important disease in India and other tropical countries. Clinical and experimental investigations, however, had shown that the missing nutrient was not Castle's extrinsic factor if defined as a substance which reacted with the intrinsic factor of the stomach to form the liver principle. In uncomplicated cases of nutritional anaemia in man and monkeys which had received no previous treatment with fractions of the vitamin B_2 complex highly purified liver extracts were inactive. The curative factor was present in crude liver preparations and in autolysed yeast extracts, but had not so far been identified. Since it was effective when administered parenterally it was unlikely that the intrinsic factor of the gastric juice was involved.

Dr. F. **PRESCOTT** questioned whether the vitamins synthesized in the human intestines were efficiently absorbed or were for the most part excreted in the bacterial debris of the faeces. He recalled that milk protected against pellagra, though little different from maize in its nicotinic acid content. This suggested that its good influence was due to its effect on the intestinal bacteria. It was an interesting point that the mental symptoms caused by the suppression of the intestinal bacteria with sulphaguanidine should resemble those characteristic of pellagra.

Dr. L. J. **HARRIS**, who presided during the afternoon session, commented on the extent and importance of recent developments in research on the vitamin B complex. A remarkable feature had been our familiarity with five members of the complex—namely, nicotinic acid, riboflavin, *p*-aminobenzoic acid, choline, and inositol—before their significance as vitamins had been recognized. Other vitamins, however, such as aneurin, with its bridged iminazole and thiazole rings, turned out to be chemical " novelties " with highly unusual structures. More knowledge on human requirements for B vitamins and on methods for the clinical recognition of the results of deficiency was urgently needed.

A national conference on maternity and child welfare has been arranged by the National Association of Maternity and Child Welfare Centres and for the Prevention of Infant Mortality, on behalf of the National Council for Maternity and Child Welfare. It will be held at Friends House, Euston Road, N.W., on Thursday and Friday, June 28 and 29, and the Minister of Health will give his presidential address at 10.30 a.m. on Friday. The subjects for discussion are: (1) nutrition as it affects the well-being of expectant mothers and of children; (2) the importance of maintaining the unity of the maternity and child welfare services; (3) the State and the parent in relation to the child. Tickets, 3s. each for one day, 5s. each for two days, may be had from the secretary, Miss M. R. Lovelock, Carnegie House, 117, Piccadilly, London, W.1. A clinical course for medical practitioners attending the conference has been arranged by the Maternity and Child Welfare Group of the Society of Medical Officers of Health for the morning and afternoon of Saturday, June 30. Particulars and tickets will be sent on application to Dr. Miriam Florentin, Town Hall, Church Street, Stoke Newington, N.16.

Correspondence

Dangers of Caudal Analgesia

SIR,—Dr. FitzGerald and Dr. Galley (May 12, pp. 677–8) are apparently enthusiastic advocates of continuous caudal analgesia in childbirth. The former, after attending the course in continuous caudal analgesia by Drs. Hingson and Edwards in Philadelphia, regrets that with one exception he can find no evidence of active interest in the method in any British hospital. Dr. Galley charges British obstetricians with prejudice, apathy, and conservatism in their attitude towards, and ill-informed criticism of, "newer methods of securing analgesia," by which, judging from the context, he apparently also means continuous caudal analgesia.

Dr. FitzGerald admits that the method "does somewhat alter the normal course of labour." This is putting it mildly, for the patient, besides being unable to empty her bladder, has no urge to bear down or use her abdominal muscles in the second stage of labour, and in consequence normal flexion of the head and rotation of the occiput are seriously interfered with, so that the second stage is prolonged and persistent occipito-posteriors and deep transverse arrests are common. FitzGerald, Thomson, and Brown found that the incidence of forceps delivery was increased to 70% compared with 12% in 1939 (before caudal). Siever from experience of 1,200 cases found that persistent occipito-posterior cases occurred in 12% compared with 4% before caudal. Hingson and Edwards report a similar experience. Infection at the site of injection is another risk. Hingson and Edwards have reported one death from this cause. Siever has had two such cases. One of the women got arachnoiditis; a laminectomy was done. The patient is "gradually recovering bladder function and the use of her legs, but the prognosis is guarded." As for the effect on the baby, in one of Siever's cases the foetus died *in utero* 5 minutes after the third injection. Within 2 minutes the foetal heart sounds became slow and gradually got weaker and stopped. In Siever's opinion this death and the deaths of three other babies in his series were due to the drug injected (metycaine).

The subject of continuous caudal analgesia in obstetrics was discussed very fully at a meeting of the Chicago Gynecological Society in October, 1943 (reported in the July, 1944, number of the *American Journal of Obstetrics and Gynecology*). In that discussion Huber mentioned 2 cases of his in which metycaine was given for Caesarean section. After 30 c.cm. of a 1.5% solution had been injected vasomotor collapse occurred. The blood pressure fell to 60/40 and so remained for 3/4 hour. The foetal heart sounds fell to 60. The baby after delivery proved to be not normal. At the time of the discussion it was 7 months old and very definitely abnormal. In another case of Caesarean section the patient also collapsed. The foetal heart sounds fell to 50 or 60 and remained so for 1/4 hour. After delivery it made one or two respirations and then could not be resuscitated. Baptisti—whose paper, by the way, every enthusiast for, or would-be user of, caudal analgesia should read—considered that though the risks of continuous caudal analgesia could be minimized by caution they could not be entirely eliminated. Among the risks he emphasized was intradural injection, with respiratory failure and sudden death. This might happen in the most experienced hands. Sudden death might occur apart from intraspinal injection. "A press campaign in the United States represents caudal anaesthesia as safe and painless childbirth. . . . The movement has to some extent stunned the medical profession to the point of clouding its judgment." Now "physicians are beginning to awake to actual facts . . . caudal anaesthesia is no safer to-day than it ever was. . . . The use of such a hazardous procedure *electively* to relieve the usually innocuous pains of labour is unjustifiable. Since the recent advent of continuous caudal analgesia four women have lost their lives because of the procedure *per se*. There have been other 'close calls' reported. . . . Never before has the human nervous system been subjected to the action of such prolonged concentrated anaesthesia. The absence of residuals and sequelae remains to be proved." Because of the death of the one-hundredth obstetric patient receiving caudal analgesia two minutes after injection the method was abandoned in Johns Hopkins Hospital, Baltimore, in 1940. "It seems strange," says Baptisti, "that the tragic accidents are so frequently delayed but apparently they eventually do occur."

An ideal analgesic in childbirth should be safe for mother and child. Judging from these reports continuous caudal analgesia is safe for neither. That is why it has never become popular among British obstetricians, not because its use calls for "increased time and skill from the obstetrician and anaesthetist" nor because of apathy, conservatism, and prejudice, as Dr. FitzGerald and Dr. Galley respectively assert.—I am, etc.,

Obstetrical Unit, U.C.H. Medical School, W.C.1. F. J. BROWNE.

Skin Cover of Wounds

SIR,—Major-Gen. W. H. Ogilvie in his valuable survey of our experience of war surgery and the adaptation of this experience to civil practice (May 5, p. 619) is concerned in a statement of surgical principles. There is one principle, however, in the skin cover of wounds that he omits and which I believe deserves notice. It is that the skin cover of wounds must be generous enough to allow full functional recovery; particularly is that important in wounds of the extremities.

I am a little afraid, therefore, of the practical interpretation of his statement that "a certain amount of tension may be used to approximate the skin without danger." An unqualified application of this principle will lead to indifferent functional end-results. From the experience of mistakes I have made and observed, adequate skin cover is essential to good functional end-results. Recently I have seen three patients who had previously been treated by delayed suture of wounds of the popliteal fossa, sutured undoubtedly with "a certain amount of tension." The wounds had healed but the scars were responsible for a considerable deformity and great restriction to the function of the knee-joint. Only when these scars were excised and the knee fully extended was it possible to assess the true skin defect. Full return to function followed the making good of this skin defect by skin graft.

Nowhere in the body is the principle of adequate skin cover more important than in the treatment of wounds of the hand. For example, a wound on the dorsum of the hand, even with a considerable skin loss, may be closed by delayed or even primary suture with "a certain amount of tension" in dorsiflexion and extension of the fingers and it will heal, but the functional end-result of such a hand will be poor, and "making a fist" impossible.

One of the big lessons of this war, I would suggest, is the value of early and adequate skin cover to wounds of the extremities with skin loss, so that full function is quickly regained after healing. The importance of valuating the area of skin loss before closing the wound should be emphasized. For example, the popliteal fossa should be examined with the knee fully extended; the axillary wound with the shoulder in full abduction; wounds of the dorsum of the hand with closed fist and the wrist slightly flexed. If the wound edges under these conditions approximate, only then is suture preferable to grafting.—I am, etc.,

Birmingham Accident Hospital. WILLIAM GISSANE.

Treatment of the Recently Starved

SIR,—I would like to record my experience with a recently repatriated prisoner of war who was making very poor progress even on the double rations and sedulous care of his family. He had not been able to digest his food, which had caused him discomfort, flatulence, and nausea, and he had not been gaining much weight.

Some simple and well-known adjuvants to the digestive processes having made a vast improvement, I make bold to pass them on, as possibly other doctors faced with the same problem may be glad of the suggestions. I have given one 2½-gr. tablet of "taka-diastase" to be chewed during the meal. At the end of the meal a dose of the following mixture: glycerin. acid.

pepsin. ʒii; tr. zingib. et tr. gent. co. āā ♏x; aq. menth. ad ℥ss. Half an hour after the meal 2 tablets of "trypsinogen." gr. 5; at night a tablet of "veracolate," a preparation of ox-bile salts. I have told the soldier that he could eat whatever he felt inclined to take.

Having observed immediate and dramatic improvement in this man's comfort and a splendid gain in weight, I have felt it was well worth while bringing forward my experience, as there are thousands of soldiers recently freed who deserve the best we can give them. Fortunately I had by me plenty of the enzyme materials for my cases, but I understand that the supply is very limited, and if other doctors less well supplied were inclined to prescribe such treatment it would be impossible for them to do so. It seems illogical to expect glands which have lost capacity from long disuse to regain functional power without themselves being renourished, which is only possible if their part in the digestive process is done artificially. The supply of enzyme materials should, in my opinion, have a very high priority at the present moment.—I am, etc.,

Cirencester. J. H. GROVE-WHITE.

Transfusion Service

SIR,—As the result of blood donors' generosity during the war ample supplies of whole blood and plasma have been available for the treatment of civilian patients in hospitals, with the result that the staffs of hospitals have grown accustomed to unstinted supplies. On the basis of the past two years we have used at this hospital approximately 1,000 pints of blood and 1,000 pints of plasma annually, but the number steadily increases. This works out at 2.5 pints of each per occupied bed and the bleeding of approximately 4,000 donors per annum.

While it is possible that a substitute for plasma may be forthcoming, it is difficult to imagine a future when whole blood would not be required. Blood transfusion is one of the most valuable therapeutic measures available, but like other treatment it costs money and must be paid for. Questions to which would like an answer are these:

1. Can an adequate supply of blood donors be obtained without payment and/or pressure on relatives and friends of patients to supply blood?
2. How far should the personnel employed in bleeding, grouping, and administration of the service be on a voluntary basis?
3. Are we to continue to enjoy the valuable aid of the Ministry of Health in the processing of plasma and the supply of apparatus? Can we rely in the future on the help of special laboratories, such as the Galton Laboratory at Cambridge, to help in elucidating grouping problems?

These are questions which must be common to many transfusion officers, and now with peace in Europe demand an early and satisfactory solution.—I am, etc.,

East Suffolk and Ipswich Hospital. E. BIDDLE, Transfusion Officer.

Artificial Respiration

SIR,—Dr. E. Clark Noble (May 5, p. 643) points out the anger of delay in instituting artificial respiration. It would e well to stress the importance of the other two basic principles:

1. *Maintenance of a Clear Airway.*—I was recently called to patient recovering from an anaesthetic. He was black in the ace, the nurse pinning her faith to oxygen blown on to his ace. When the jaw was pulled forward the obstruction was relieved, and the patient breathed at once.

2. *Adequate Pulmonary Exchange.*—The choice of any one particular method of effecting this is of little importance compared with the skill of the operator. If the patient is dead no method will avail; if there is a spark of life it is probable any ethod, properly carried out, will be successful.—I am, etc.,

Nuffield Department of Anaesthetics, Oxford. R. R. MACINTOSH.

Civilian Mass Radiography

SIR,—The stimulus of your leading article (April 14, p. 521) ould bring in sufficient accounts of the working methods of me of the civilian units to furnish material for a résumé on is subject. The work now being done may not then appear ite as haphazard as was suggested originally.

There is little doubt that the best practical use for a mass radiography apparatus allotted to a large county area, such as Lancashire or the West Riding of Yorkshire, is that outlined by Dr. Lissant Cox (April 28, p. 605)—i.e., that the mass radiography service should act as a diagnostic outpost and work in the closest co-operation with the tuberculosis dispensaries in the several areas. It is clearly impossible for a constantly moving outfit in a large district to do its own follow-up work —e.g., when cases discovered at factory "A" are due for a three-monthly check, the unit may be at factory "B" 50 miles away, and so on.

This unit is operated on similar lines with certain modifications devised by Dr. F. Ridehalgh, its medical director. Here the weekly clinical session held at the factory is a joint one, where the medical officer of the mass radiography service and the tuberculosis officer of the local area see the cases together. If it is not possible to come to a diagnosis at once, and if, as with these early symptomless lesions, further investigation and observation are necessary, the tuberculosis officer arranges for this at his own clinic. There is, therefore, no question of a "snap diagnosis" being made on the spot. Institutional treatment is not advised unless there is clinical indication of activity or radiological evidence of spread—i.e., after repeat *x*-ray examination. The situation is carefully explained to the examinees, and in our experience hardly any have demurred over attending the clinics for a periodical check.

The joint clinic provides the medical officer in charge of the unit with first-hand information of the line of action to be taken on all mass radiography cases passing into the care of the tuberculosis officer. The vital matter of follow-up of all possibly significant lesions discovered by mass radiography has always been provided for. The Leeds Tuberculosis Clinic sends to the mass radiography service periodic reports of all cases referred to them. When any radiological change is noted in the follow-up films, there is every facility for the inspection of these films and the case notes by the mass radiography medical officer. The tuberculosis authorities in the West Riding are proving equally co-operative.—I am, etc.,

MICHAEL G. MAGAN,
City of Leeds Mass Radiography Service. Assistant Medical Director.

Tuberculosis of the Lower Lobe

SIR,—I found Dr. Raymond C. Cohen's article on tuberculosis of the lower lobe (May 12, p. 662) of great interest, particularly his statements on middle-lobe lesions. He mentions the treatment of a number of cases of mid- and lower-lobe lesions by phrenic paralysis followed by pneumoperitoneum, and concludes: "The results so far have been very successful, particularly with middle-lobe cavities and cavities in the middle or periphery of the lower lobe."

In contrast to Dr. Cohen's finding, however, are those mentioned in an annotation on artificial pneumoperitoneum in the *Lancet* of April 28 (p. 534). Here it is stated that Rilance and Warring (*Amer. Rev. Tuberc.*, 1941, **44**, 323), in their 55 cases of artificial pneumoperitoneum with phrenic crush, noted that the best results were obtained in lower-zone cavities, next best in upper-zone cavities, and *worst in mid-zone cavities* (italics my own). Clifford-Jones and Macdonald (*Tubercle*, 1943, **24**, 97) agree with these findings.

There is, of course, an anatomical explanation in keeping with these clinical findings. In the book *Pulmonary Tuberculosis* by Kayne, Pagel, and O'Shaughnessy (Oxford University Press, 1939) it is stated (p. 393) that, "provided the pleura is free, paresis of the diaphragm curtails or even abolishes the ventilating function of the lower lobe of the lung but leaves the function of the upper lobe undisturbed. The position, however, is quite different when, as a result of an old inflammatory process, adhesions have obliterated the interlobar sulcus; for under these conditions paresis of the diaphragm has a very definite effect in limiting ventilation of both lobes of the lung. In view of these facts the old controversy as to the effect of phrenicectomy on lesions in the upper lobe has been brought to an end. An effect will be produced if the lobes are adherent and the interlobar septum obliterated."

In a chronic disease of such protean manifestation as pulmonary tuberculosis these conflicting opinions confuse one as to the value of a particular method of treatment. Permanent control of the disease is, of course, our ultimate objective, and symptomatic improvement alone, no matter how satisfying at the time, if of no great importance in the final analysis. We must therefore distinguish between temporary control of the disease and permanent arrest of the disease. Dr. Cohen mentions that "the results *so far* [italics my own] have been very successful," and one can only conclude that a further communication will be necessary to decide whether or not the final results were as successful.—I am, etc.,

Preston Hall Sanatorium,
nr. Maidstone.
GEORGE R. W. N. LUNTZ.

Prolapse of the Rectum in Women

SIR,—The article by the late Mr. Harold Chapple (May 12, p. 661) draws attention to the successful treatment of a rectal prolapse in a woman by operating from the abdominal approach. Dissatisfied with the outcome of various operations performed *from below* and following the recommendation of R. R. Graham (*Ann. Surg.*, 1942, **115**, 1007) I carried out a similar procedure lately on a single woman; an epileptic aged 38, who was still having severe fits and had suffered from rectal prolapse for years. Five inches or so of bowel protruded on straining, despite surgical treatment elsewhere three years before. The peritoneum of the pouch of Douglas was incised, the fascia covering the levator ani muscles was brought together by sutures deeply placed *in front* of the rectum, and the peritoneal pouch obliterated by a further tier of sutures above the first. The principle of the method is based on the assumption that a complete rectal prolapse is essentially a sliding hernia of the anterior wall of the rectum (Jeanell). Additional support was obtained by anchoring the colon to the lateral pelvic wall near the brim; this step was possibly unnecessary. To avoid injury to the ureters these were identified before placing the sutures. Shock was not a conspicuous feature of this operation, which was performed under general anaesthesia; and the after-course was uneventful; the bowels, with the aid of liquid paraffin, acted on the fifth day. It is too early to pronounce on the ultimate result, but the immediate effect has been very gratifying.—I am, etc.,

St. Andrew's Hospital, E.3.
J. R. M. WHIGHAM.

Women in Labour

SIR,—I fully endorse the remarks of Dr. John Elam (April 7, p. 495) on gas-and-air analgesia and on the apparent indifference to the suffering of women in labour which still exists among both doctors and midwives. General practitioners as a whole seem satisfied to rush, at the last possible moment, to arrive as the baby's head is about to be born and to administer a few drops of anaesthetic. Is the doctor's satisfaction shared by the patient? As a rule the only women fortunate enough to receive any analgesic are cases of abnormal labour. The penalty for a normal labour is having to go through hell unaided.

Perhaps doctors may justify their indifference by quoting Dr. Dick Read's doctrine that normal labour is painless, but the essence of Dr. Read's teaching is that doctors must take more time and trouble in instructing and measuring childbearing women. He would be among the last to claim that normal labour in the average unenlightened and unaided woman of to-day is painless.

For the present "lamentable state of analgesia in labour" Dr. A. H. Galley (May 12, p. 678) suggests five reasons: apathy, conservatism, prejudice, lack of apparatus or facilities, and lack of anaesthetists. I would like to add another: inability to do a rectal examination. When giving analgesics in labour it is essential to know how far on the patient is, and to be able, if necessary, to check subsequent progress. The objection that this requires extra P.V. examinations would be sound were it not that rectal examination is available, and is quicker, less dangerous, and may be repeated as often as necessary. With practice a P.R. is almost as informative as a P.V. without an anaesthetic, and I consider that to master the art of doing a P.R. is a necessary preliminary to safe and satisfactory analgesia.

Dr. J. K. B. Waddington (May 12, p. 678) comments on the difference between "the callous attitude" of some institutional midwives and the sympathetic co-operation of most domiciliary midwives towards relieving the pains of labour. Surely the reason is obvious? The relatives and friends of a patient confined at home usually abound in sympathy for her, and, though often exasperating to the nurse and doctor, their concern does result in extra consideration for the sufferer.

To give analgesics in labour necessitates an extra visit or two to the patient's bedside, but the grat tuce of the mother in itself is ample reward for the extra trouble. Anything really worth while requires extra effort. Surely the falling birth rate would be arrested and the willingness of women to have more than one baby would increase if, with help, labour ceased to remain in their memory as an unforgettable nightmare.—I am, etc.,

Reading.
K. D. SALZMANN.

SIR,—I should like to express my agreement with Dr. J. K. B. Waddington on the subject of women in labour. As a student I acquired a permanent dislike of obstetrics because of the callous attitude of the midwives towards the patients, and the consequent unnecessary suffering which I was forced to witness. The midwives would refuse to give even the simple analgesic mixture which they were allowed to administer without a doctor's permission. We students had many altercations with them on the subject; the commonest argument they used was: "Women have had children without anaesthetics for thousands of years." When we asked them whether they would apply the same argument to the reduction of fractures, for example, they had nothing to say. They are particularly unkind to the nervous type of patient with a rigid cervix and ineffectual, but often agonizing, pains, their attitude being, "Fancy making all that fuss over such little pains."

When I did my midwifery training the maternity wards were closed owing to the blitz, and any woman who remained in London had to have her baby at home. I remember asking the district midwife to show me how to use the Minnitt machine, which they were compelled to take out with them. She replied: "Oh, I don't believe in that; they have better pains without it. I just give them the mask without turning on the gas." The net result was that every woman, primiparae included, went through her labour from start to finish unaided.

Why do all women of the higher income levels employ doctors rather than midwives for their confinement? The reason is that they thus ensure at least some measure of relief from their pain. The great majority of women will continue to suffer until midwifery comes completely under the control of the medical profession instead of that of the Central Midwives Board.—I am, etc.,

London, W.8.
ANGELA HEFFERMAN.

SIR,—Having recently spent seven weeks in maternity hospitals as a midwifery student, I should like to confirm the strong criticisms which have been directed against the inadequate analgesic measures employed in labour. During my course I conducted twenty-six deliveries, and either assisted at or witnessed, thirty-two others—a limited but probably representative sampling. It came, indeed, as a profound shock to me, after the pious injunctions I had read in textbooks, to find that "analgesia in labour" was more often a polite fiction than a reassuring fact.

I am sure that administrative and economic difficulties are largely to blame. Six weeks of my studentship were spent in council hospitals which were obviously suffering from lack o staff. Yet my remaining week, passed in a world-famous voluntary maternity hospital, has no lurid or harrowing associations. The labour ward on the occasion of a delivery swarmed with nurses, each of whom had a definite duty to perform while the analgesia obtained seemed to be highly efficient though nothing more elaborate than the Minnitt machine was employed.

Unfortunately, lack of staff at one of the council hospital was combined with lack of apparatus, since the Minni machines were either absent or defective in mechanism. Stil more unfortunately, this want of staff and gear tended to breed in the midwives a "rationalization" of the circumstances, s that they would exhort the luckless mothers, more common in anger than in pity, to show a fortitude which should neve have been necessary. Any protest could be met by the conte tion that analgesia was superfluous because labour was "physiological process." So, I suppose, is cutting a wisdo tooth, but would any sane person deny the sufferer aspirin on that account?

I doubt whether one can justly accuse the average midwife of taking a wanton delight in the spectacle of pain (it surely goes without saying, of course, that no sadist should be allowed to practise medicine or nursing); but I am afraid midwives can very easily acquire the habit of excusing the lack of analgesic facilities on the pernicious and illusory principle that the pain of labour is something which should be endured for its own sake. This discredited metaphysical concept of the virtue of physical suffering *per se* is certainly one which should never find a place in the practice of medical science.

Finally, it is only right to mention that certain "difficult" women seemed to make the task of the midwife particularly arduous, and that the threshold for pain stimuli has a subjective as well as an objective component. She who yells most does not necessarily feel most!—I am, etc.,

London, S.W.10. J. A. FLETCHER.

Decay of Teeth

SIR,—Sir Edward Mellanby has maintained that the decay of teeth and rickets are one and the same problem. There is, however, much evidence against this being the case. Rickets has been reported on from North Indian districts unaccompanied by decay of teeth. Natives in general suffer from such decay only when they come to eat white flour and sugar in place of their own diet. There is said to be a district in Texas where there is no decay of teeth in people living there on the food grown in that district. It is reported that North Shields with a moorland water supply has much more tooth decay among its inhabitants than South Shields with a water supply taken from wells.

Where there is enough fluorine in the diet to produce slight mottling of the enamel there is little decay of the teeth. Fluorine is a natural constituent of the teeth, and the traces of it found in wheat are removed on separating off-white flour. The washing of wheat in the roller-milling process not only leads to fermentation of the germ and the need for separating this from flour but removes traces of those imponderable metals which are found in soil and are needed for health. The excessive cleaning of vegetables, peeling of potatoes, etc., must also remove these imponderables. The substitution of reservoir water for well water, while protecting us from disease such as typhoid and cholera, has also removed these imponderables, the need for which is shown by researches on domestic animals.

Much has been made of laboratory experiments which show
hytic acid present in whole wheat lessens the absorption

Clinical evidence shows that vast numbers of patients carry pulpless teeth with no signs of ill-health. It is, however, a fact that some pulpless teeth act as dangerous septic foci. Careful clinical and radiological investigation coupled, if need be, with consultation with the patient's physician and a pathologist should enable a dentist to separate pulpless teeth into two classes—one containing all the dangerous cases and another to which a "clean bill" can be given. It is quite true that if all pulpless teeth had been removed some people would be alive who are now dead; also if all tonsils and appendices were removed in childhood much serious trouble would be avoided.

The treatment of pulpless teeth that are judged suitable for retention is a matter of great importance, and unless a dentist is prepared to give the care indicated by the researches of Prof. Sprawson and others he should not undertake such treatment. Until the correlation between various kinds of ill-health and various classes of pulpless teeth has been settled by teams of expert workers, I feel that dentists are doing good service to the community by preserving a certain number of pulpless teeth on the lines I have indicated.—I am, etc.,

Technique of Venepuncture

SIR,—I was much interested in the article by Dr. Mendelssohn and Prof. Witts on transmission of infection during venepuncture for withdrawing blood (May 5, p. 625). I have known Prof. Witts for many years, and have the greatest respect for his opinion, so I am sure he will not be offended if I suggest that his technique of venepuncture is faulty. He states that the tourniquet must be released before the needle is withdrawn, but I would maintain that this should never be done until the needle is taken out. With a proper technique no haematoma will result.

The method I have used for the last twenty years is as follows: The needle is inserted as usual, after distending the vein by means of a tourniquet, and the blood is drawn into the syringe by traction on the piston. The last few millimetres may be allowed to enter passively. A pledget of wool soaked in the skin-cleansing agent is then lightly held over the puncture area and the needle is withdrawn. Simultaneously firm pressure is made on the pledget of wool. Still holding this with one hand, the operator puts down the syringe and uses the hand thus released to unfasten the tourniquet. This is easily done, as the tourniquet consists of a piece of rubber tube with a spring clip attached to one end. The patient's arm is then flexed as far as possible and left thus for three minutes.

I may mention that I have used this technique to collect blood for sedimentation rate into an unsterile syringe for over fifteen years, during which time some forty to fifty thousand such estimations have been made, and there has so far (touching wood) been no single case of jaundice or resulting trouble of any kind. I think, on the other hand, that if unsterile syringes are used, two-piece glass syringes are to be avoided, as the plungers nearly always run too easily, even when they are new. We reserve these for dry-sterilizing and use them for other purposes than sedimentation rate. For the latter we use Record syringes that fit well. If the pistons run too easily the piece of spring-wire that encircles the piston in the groove in its centre is
nded to fit the bore more closely and thus act as a

in 1930. They were vaccinating a group of boys at the Naval School, Greenwich. I do not know if a record of their work exists. I have used the multiple-pressure method on all occasions since that demonstration.—I am, etc.,

Ilford. JOHN SPENCER.

Soya Bean and Allergy

SIR,—Soya bean was originally used in the East to make a special sauce by a long process of fermentation. Years ago I obtained a big reaction to it in a Siamese patient who suffered from asthma. To-day it is imported by thousands of tons and is used in very many articles of food. In virtue of its whiteness it is the chief ingredient in salad cream, in wartime cream substitutes, especially in ice-creams. As a thickening agent it supplants wheat and cornflour in thick soups, gravies, and sauces. In the dry form it is found in many proprietary articles of food and may be in margarine.

Being in such general use soya bean should be on the list of common foods for which those treating allergy test their patients in the routine way. Recently I found a small chil suffering from an infantile eczema to be particularly sensi to this bean, responding with a very big reaction when test the scratch method. Unfortunately there is so much so in use that avoidance is impossible and desensitizatio carried out as for dust and other unavoidable pr

In conclusion I think we may expect sensiti bean to become of increasing importance.—I

were less than 30 weeks pregnant when they had their first attack of pyelitis, and 13 over 30 weeks pregnant. In 30 of these 50 patients the urine was sterile after a course of sulphonamides; 3 had a recurrence—one at the 32nd week and two at the 36th week. In 20 of the 50 patients the urine was not sterile after a course of sulphonamides; one patient had a recurrence at the 32nd week of pregnancy. Presumably it was to this last group of patients that Dr. Eadie would have given the small doses of sulphonamides, but in this small series the recurrence rate was higher among those in whom the urine had become sterile than among those who still had infected urine, and in both groups the recurrence occurred after the 30th week.

During the years 1927 to 1944 inclusive there have been 284 patients admitted with pyelitis of pregnancy: 197 were less than 30 weeks pregnant and 87 more than 30 weeks pregnant when the first acute attack occurred.—I am, etc.,

An Examination Paper for Nurses

SIR,—We wish to protest emphatically against the examina-ion paper on medicine and medical nursing treatment set in he recent final State examination by the General Nursing ouncil for England and Wales. In our view the examination aper was distinctly unfair for the following main reasons:

1. None of the questions concerned treatment or nursing.
2. Questions 2 and 3 required information about *investiga-ons* of the causes of haematuria and dysphagia. Such investiga-ons are highly technical, no part of a nurse's duty, and she ould never have to undertake the responsibility of advising r performing them.
3. A paper consisting of one obligatory and one alternative uestion cannot be regarded as a reasonable test of a nurse's nowledge of medicine and medical nursing, even if the ques-ons themselves were unexceptionable.

We feel very strongly that nurses should not be subjected to xamination papers of this kind, which clearly demand in-ormation that could reasonably be expected only from those udying for medical qualification.—We are, etc.,

Rheumatism and Orthopaedics

SIR,—Having taken a very small part in the formulation of e scheme of training suggested for physicians interested to ake the study and treatment of rheumatism their life work, d which has been expanded by the committee of which r Adolphe Abrahams was the chairman, I am particularly erested in his report which you published (*Journal*, May 12). s an orthopaedist who has had a good deal to do with heumatism," perhaps I may be allowed to question the sdom of Sir Adolphe's suggestion for substituting the title "orthopaedic physician" for "rheumatologist." As he has own so well in the explanatory section of his article, the ord "rheumatism" is loosely used by laymen and doctors ke for almost any condition the cause of which is unknown. is certainly undesirable to have a group of specialists called heumatologists" who, knowing more and more about aetio-gical obscurities, are perhaps going to dabble in a multitude quasi-medical, quasi-surgical procedures. For—let me come ickly to the point—are we not really in need of more really od physicians: just simple honest-to-God physicians? The uble is that the physicians, who recently have become so utely aware of the seriousness of the problem of rheumatism this country, have been inclined to judge of what is being ne only by the standards of the large city general hospitals. rthermore, in these quarters there is a tendency to place due emphasis on the surgical aspects of the orthopaedist's rk. It is true that for convenience the growth of ortho-edics has been largely within the arm of medicine called surgery, but it is a true example of a surgical science which has had to take a broad medical outlook, and its whole history is one of care for the whole patient rather than of one small part. The big city hospitals have little idea of what has been done over the past thirty years in the great provincial orthopaedic schemes founded by Sir Robert Jones and maintained by his followers. It would be better to call us "orthopaedists," for surgery is a relatively small part of our job. In connexion with rheumatism we do know a good deal about the human problem involved, and, in fact, in the regional orthopaedic schemes we have a very important organization which has anticipated the Empire Rheumatism Council's "Plan for National Action."

These provincial orthopaedic schemes have been prepared to assume the long-term treatment of chronic joint disease, to provide continuity of treatment in a special service in both hospital and dispersed out-patient clinic, having teams of expert technicians in orthopaedic nursing, physiotherapy, training, and rehabilitation. This has been done with unity of control. The whole problem has been considered in all its aspects, providing for the care of the patient as a whole by psychological encouragement in hopeful surroundings, planning for the prevention and correction of deformity and the maintenance and restoration of function. The protection of active joint lesions has been given with suitable apparatus and the graduation of activity: in other words, true physiological rest, with a follow-up scheme after leaving hospital to ensure so far as possible that treatment is maintained. In this milieu a most important possibility for training can be provided, and the scheme must be expanded to fill the deficiencies, which generally are in the direction of more beds and more staff. In the orthopaedic hospitals, what is needed is the help of more general physicians. They do not need to dabble much in orthopaedics. We are fully capable of doing that. There is nothing in the services of such a physician which cannot be provided by an interested general physician, as those of us know so well who are fortunate in having available such people.

One of the diseases of modern life is to invent new names for old things that people have lost the understanding of. Laziness of mind and failure to utilize past lessons are largely responsible for the present excitement about "rehabilitation." Let us be very careful before starting a new fad of the "orthopaedic physician."—I am, etc.,

Exeter. NORMAN CAPENER.

Cataract Surgery

SIR,—In a review of a book on cataract (May 12, p. 665) the statement is made that surgery "can do little for many patients who suffer from severe decline in vision without reaching the stage where operation is either justifiable or feasible."

Surely such a pessimistic view of modern cataract surgery is not in accordance with present-day clinical experience. The statement indicates an undue scepticism of the possibilities of cataract surgery. Operation is always both justifiable and feasible in the case of a patient, who suffers from severe decline in vision, at any stage, and it is difficult to imagine any reason, apart from complications unconnected with the eye, why operation should not be undertaken in such patients. It is to be hoped that we have passed the day when patients with senile cataract are asked to wait until the cataract is "ripe" befc they can be relieved by surgery.—I am, etc.,

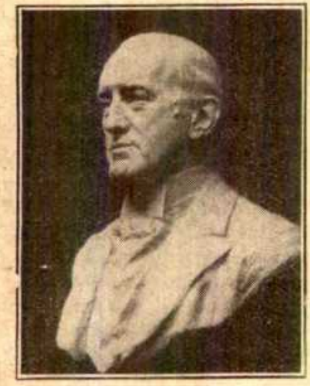
Obituary

SIR STANLEY WOODWARK, C.M.G., C.B.E., M.D., F.R.C.P.

Arthur Stanley Woodwark, who died on May 11, aged 70, was the third, and last survivor, of the six sons of the late George Woodwark, a North Riding man who had married a Norfolk lady, settled at King's Lynn, and become very prominent in the public life of that town and of Norfolk. Another of the brothers, the late Lieut.-Col. G. G. Woodwark, was for a time M.P. for the town. Four of the six were of gigantic stature, and Stanley, who stood six foot four or a little more, was the tallest of them all. He was born in 1875, educated at Felsted and St. Bartholomew's, whence he qualified as M.R.C.S., L.R.C.P. in 1902. He held resident posts at the Royal Free Hospital; and before that spent a short time as ship surgeon, during which he visited the Panama Canal works, then still under de Lesseps and his French company. He used to recall his amazement at seeing vast quantities of valuable machinery, not even uncased, hurled into a bottomless swamp in order that rascally officials could draw new commissions for further orders from rascally contractors. He first went into a partnership in general practice, but, conceiving that he had been unfairly treated by his senior, gave it up and decided to specialize in medicine. This meant going back to medical study: he took the M.B., B.S.Lond. with honours in both medicine and surgery in 1906, and the M.D. in 1909. He was casualty physician to St. Bartholomew's, medical registrar at King's College Hospital, and then was appointed assistant physician to the Westminster Hospital, where he was afterwards for many years a most efficient and popular Dean of the Medical School, and ultimately senior physician. In 1920 he became F.R.C.P.



While biding his time for consulting practice, Stanley Woodwark was a highly successful coach for examinations in medicine; when he epitomized his teaching in a *Manual of Medicine*, it soon ran through four editions. On the outbreak of war in 1914 he took a temporary commission as lieutenant in the R.A.M.C.; but not many weeks had elapsed when he was promoted in one jump to lieut.-colonel, at that time an almost unprecedented occurrence. Space forbids an account of his work at the War Office; it suffices to say that he ended the war as Colonel, Consulting Physician to the Army, C.M.G., C.B.E., with a recommendation for a knighthood (which led to nothing at the time). Both before and after the war, besides enjoying a wide consulting practice, he was much occupied in life assurance work for the Pearl and other offices, and was greatly in demand as an expert witness in compensation cases. His magnificent appearance, not diminished by his immaculate dress, combined with great care in getting up his facts and a strict impartiality in presenting them to the Court, impressed favourably both juries and judges alike.

In student days Woodwark had made some mark as librettist for concerts and pantomimes; in later years this facility bloomed into a talent for after-dinner speaking which put him in the top class of this difficult art; he was also a noted raconteur, with a pretty wit of his own. In 1911 he married Hilda, youngest daughter of the late Sir Richard Robinson. She survives him with two of their three sons and a daughter; it was generally conceded at the time that they were the handsomest couple in Harley Street, and their hospitality [illegible]here and at their country home at Cowden has been [illegible] many years. He was knighted in 1932 for all-[illegible]ices; was D.L. and J.P. for London; Knight of St. John of Jerusalem; consulting physician to the Roy Waterloo and the Miller Hospitals; Master of the Apothecari Company for 1941–3; Master of the Turners Company f 1943, and of the Barbers for 1942–4; and a member of counc of the Medical Defence Union. He had been examiner medicine both for the Conjoint Board and for the L.M.S.S. He was also President of the Institute of Hygiene, and Governor of the Foundling and Westminster Hospitals. N account of him would be complete without a reference to t Savage Club, where he will be greatly missed; even in th society his personality was an outstanding one. He had bee a member of the B.M.A. since 1907, but never sought electio to the Council. Lady Woodwark has been chairman council of the Ladies' Guild of the Royal Medical Benevole Fund after long service on the council and its committees.

S. INGLEBY ODDIE, M.B., C.M.

Samuel Ingleby Oddie, who died recently at the age of 76, w one of H.M. coroners for the County of London for 27½ yea until his retirement in December, 1939: he had then held near 30,000 inquests and, to use his own words, had taken a re interest in crime and criminals for nearly 50 years.

He qualified medically (M.B., C.M.Ed.) in 1891 and spe his first few professional years as a naval surgeon. Then entered private practice in Surrey, but found that it did n appeal to him. He left medicine and read law; he was amo the top six candidates in the Bar Final and was called to t Bar by Middle Temple in 1901. He quickly established hims in his new surroundings and achieved a substantial practice the common law and criminal side. Later he entered t chambers of Mr. (afterwards Sir) Richard Muir, who was o of the senior Treasury Counsel at the Central Criminal Cou Had Oddie desired to remain at the Bar he would certain have attained eminence: probably the best-remembered ca in which he was one of the counsel for the Crown was t prosecution of "Dr." Crippen for murder. But (as he hi self has told in his book of reminiscences *Inquest*) Oddie h always wanted to be a coroner. The chance came in 1912, a he was appointed coroner to South-West London and to t City and Liberty of Westminster; the Westminster appointme was made by the Dean and Chapter, and this was the l occasion of the exercise of the franchise, which had been exta for 800 years; the right has now disappeared.

As coroner, Ingleby Oddie became an outstanding examp of the right man for that office. His basic medical educati his appreciation and knowledge of everyday affairs, and (p haps above all) his experience in the actual practice of l gave him a background that placed him in a class by hims He realized that the duty of the coroner is not, as is someti wrongly said, merely to find the cause of death: it is to asc tain by evidence when and by what means the deceased ca to his death. When in court Oddie was alert; the proceedi never dragged. He had both clarity and strength of mind; hated subterfuge in any form; he did not hesitate to expr if his were the verdict, what he believed to be the facts. was popular among his colleagues and gave great service to Coroners' Society of England and Wales, being president fr 1925 to 1927—a period of importance in view of the com into operation of the Coroners (Amendment) Act, 1926, wh effected considerable changes in procedure.

This versatile, genial, and kindly man had a keen sense humour which he turned against himself at times. His o account of his departure from the scene of his private prac was that he set up his top hat on the garden path, took running kick at it, and left. Again, at the age of 63, he fou it necessary to have a tooth removed: before his dental appo ment he held one inquest, and this happened to be a death i dental chair; Oddie used to recount how this rare event him in a suitable frame of mind at once.

He had other interests apart from his professional dutie architecture, book reading, crosswords—and he was an acc plished croquet player. He was a good friend and a most en taining companion. Despite the twinges of ill-health since retirement (which was a matter of regret to him at the ti he well maintained his capacity for expression in letters to friends. He is survived by his wife and by his son, Ri Oddie.

W. B.

GARNETT WRIGHT, F.R.C.S.

r. J. B. **Macalpine** writes:

The sudden death of Mr. Garnett Wright removes one of the st beloved and capable of Manchester consultants, and severs a k with the Salford Royal Hospital which had lasted for nearly years. Having previously served a short time as honorary sur- on to the Ancoats Hospital, Manchester, he transferred to the lford Royal Hospital in 1910, and since 1918 had been its senior rgeon. Just before the commencement of the present war Wright ached the age of 60 years, and according to the rules of the hospital, hich provide for retirement by stages up to the age of 65, he had st one-half of his beds. With the altered conditions produced by ss of honorary staff owing to the war Garnett Wright shouldered resh the responsibilities of a whole surgical unit, and, though in e latter years the strain was obviously telling, he held manfully his post until within a day or two of his death. Only a month o he had bought a house in his native county (Cumberland) to hich he hoped to retire this summer.

Wright's principal operative field was the abdomen, though he was so interested and successful in the surgery of the thyroid. His rgery was essentially practical, sound, and direct, and his results ould probably stand comparison with those of the most successful. e had a flair for diagnosis, and even though he never acquired a despread practice his judgment and advice were much in demand colleagues and friends. Though anything but easy-going in his neral surgical work he acknowledged to a certain indolence in e matter of contributions to surgical literature, with the result that ough a handful of valuable papers have come from his pen much the results of his wide experience are not recorded. This is the re regrettable as his mind was pre-eminently accurate, observant, d trustworthy.

Garnett Wright will long he remembered for his kindly ways and ready help and advice when, as often, it was asked for. His und realistic help and counsel were frequently sought by members our profession not only in professional but also in personal airs, and his judgment was rarely at fault. Customarily gentle d generous to a degree, he could be brusque and forthright if a tter of principle appeared to be involved, he himself being one the most sincere and upright of men. He was a good committee- n and a wise liaison officer between the administrative and medical ards of the hospital: in the counsels of each his opinion carried ch weight. Even though we realized that his retirement was minent his passing leaves a blank not only at the hospital but in wide circle of affectionate and appreciative friends.

We regret to announce the death on April 18 at Wrington, merset, of Dr. H. C. **Bristowe**, son of Dr. John Syer stowe, at one time senior physician to St. Thomas's Hospital, ndon, and the author of a well-known textbook on medicine. bert Carpenter-Bristowe received his medical education at Thomas's Hospital, qualifying M.R.C.S., L.R.C.P. in 1888, d taking the M.B.Lond. in 1889 and the M.D. in 1890. After number of hospital appointments he started in practice at ington in 1892 and remained there until he retired in 1926. then took up work as a medical referee in connexion with tional Health Insurance. Dr. Bristowe had a fine record of rk for the B.M.A. He was on the Council from 1919 to 33, and his record of committee work is very extensive: the ntral Ethical Committee from 1920–31; Medico-Political mmittee, 1920–31; Maternity and Child Welfare Subcom- ttee, 1920–30; Post Office Medical Advisory Subcommittee, 3–31; Prison Medical Officers Subcommittee, 1925–7; the sistant Asylums Medical Officers Subcommittee, 1926–9; the cho-analysis Committee, 1927–9; the Mental Deficiency mmittee, 1930–2; and the Private Practitioners and Mental ess Treatment Committee, 1931–2. While playing no ticularly spectacular part he was always regarded as a sound iser and a good committeeman. In 1931 he convened the ugural meeting of the East Somerset Division, Bath and stol Branch, of the B.M.A., and was its first chairman. He s a Representative from 1917 to 1923, from 1925 to 1932, again from 1934 to 1936. For some years he was chairman the Somerset Local Medical and Panel Committee. Dr. stowe was much interested in Freemasonry and took a lead- part. Among the many offices he held were those in Grand in Somerset Provincial Grand Lodges; he was also a mber of the Somerset Masters Lodge and Past Master of the dge of Agriculture. In professional life he was highly arded by his patients for his wide knowledge and the care skill he gave to them, for behind an occasional brusqueness manner he was a very warm and kind friend who instilled at confidence.

We regret to announce the death on May 4, at 32, Oakley Street, Chelsea, of Dr. **Edmund Fairfield Thomas**, aged 61. He was M.D.Bristol, M.D.Brux. (Hons.), M.R.C.S., L.R.C.P., L.S.A., D.P.H. with honours. Though for long in general practice his chief interest lay in the prevention and treatment of tuberculosis, and he wrote a "History of the Anti-tuberculosis Movement in Wales" which appeared in the *British Journal of Tuberculosis* in 1911. He was one of the first school medical inspectors in Wales, and the first tuberculosis officer to be appointed in that country. He founded the first municipal dispensary for the treatment of consumption. During the 1914–18 war Dr. Fairfield Thomas served with distinction as a naval surgeon with the Dover Patrol and the Grand Fleet. He was a well-known and highly respected figure in Chelsea, and during the present war he rendered steady service in the air raids in the borough. He was an active Freemason and a Past Master of the Middlesex Hospital Lodge. Dr. Fairfield Thomas was an ardent worker for the B.M.A., of which he became a member in 1906, and was for many years the life and soul of the Chelsea Division. He was chairman of the Division from 1933 to the time of his death, and represented it at the Annual Representative Meetings 1921–6, again in 1930, 1932, 1941, and 1943. He leaves a wife and two sons, the elder of whom is continuing the practice.

On May 10, his 83rd birthday, Dr. **James Herbert Menzies**, of South Kensington, died in the house where he had carried on practice for a very long period of years; indeed, when he retired he was probably the senior in standing of any practitioner in that district. He was a brother of the late Dr. H. H. Menzies, of Westminster; both the brothers had been cricketers of more than common skill, though J. H. had not quite the same reputation as H. H., who was a Middlesex county player. He was trained at St. Bartholomew's Hospital Medical School, whence he became M.R.C.S., L.S.A. in 1884. Thereafter he did resident appointments at the West London Hospital before settling in general practice in Kensington. During the 1914–18 war Dr. Menzies held a number of part-time appointments in temporary war hospitals. A man of quiet disposition and very strictly upright and honourable principles, he gained the respect and affection not only of a wide circle of patients but of his professional colleagues as well. His impressive figure and dignified bearing will be much missed in the Hereford Square neighbourhood.

Dr. **Kenneth James William Craik** has died in Cambridge as the result of a cycling accident at the early age of 31. A brilliant psychologist, he had done valuable work on behalf of the fighting Services. He went to Edinburgh University from the Edinburgh Academy and graduated M.A. with first-class honours in philosophy in 1935. He gained the Hamilton Fellowship and in 1936 the Shaw Philosophical Fellowship, and then went to St. John's College, Cambridge, for a research course, leading to the Ph.D. in 1941 for his thesis in physiological psychology entitled "Visual Adaptation." He was elected a Research Fellow of St. John's in 1942, and during the war did research work for the Air Ministry and other Service Departments. In 1944 the Medical Research Council appointed him director of its Unit for Applied Psychology at Cambridge. Dr. Craik was the author of a book, *Nature of Explanation*, published by the Cambridge University Press two years ago, and of articles in the scientific journals, including a paper on "Specifications for Dark-adaptation Tests," published in the *British Medical Journal* of May 22, 1943. He was a Fellow of the British Psychological Society and a member of the Physiological Society. His untimely death robs science of a worker who had already done much for his country and for the application of psychological knowledge to particular problems.

Mr. A. P. Bertwistle writes: May I add to your obituary notice of Mr. **Lawford Knaggs** a few observations on the man. Your note dealt with his work. He was above all a gentleman whose rugged, gaunt exterior hid a heart of pure gold. In Leeds he always gave the impression of being a lonely man whose sole object in life was the curing of disease. In the last world war, no matter at what time of the night the convoys of wounded arrived he was there to welcome them with a smile of encouragement. His large hands were gentleness personified. A fellow student of mine, R. Graham, who broke his femur, declared that "Pa" Knaggs—as he was affectionately called—was the only one who could examine a fracture without pain. While his book on bone was a magnificent piece of work, a series of about half a dozen more articles on bone disease in the *British Journal of Surgery* were even finer. His command of the English language was perfect and he was scrupulously careful in his use of words. I, personally, shall miss him greatly, as no accounts of bone were published in *A Descriptive Atlas of Radiographs* without his approval.

Universities and Colleges

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Gift from the B.M.A.

As announced in the Annual Report of Council printed in the *Supplement* of May 12, the Council of the British Medical Association has contributed 1,000 guineas from Association funds to the Restoration and Development Fund of the Royal College of Surgeons. Since then the Secretary of the Association has received the following letter from Sir Alfred Webb-Johnson, President of the College:

> MY DEAR DR. HILL,
>
> I beg to acknowledge with thanks the receipt of your letter informing me that the British Medical Association is making a donation of one thousand guineas to the Restoration and Development Fund of the Royal College of Surgeons. This spontaneous gesture is very deeply appreciated by my Council, and it will be welcomed by all the Fellows and Members of the College.
>
> It is a great encouragement to us in our work to receive the support of your great Association, which is representative of the whole medical profession. The gift is welcome not only for the substantial help which it will give towards the objects we have in view, but also as further evidence of the cordial relations between the Association and our College. It has been one of the happiest experiences of my period of office as President of the College to have had such friendly relations and such fruitful co-operation with the British Medical Association.
>
> I would like you to assure your Council that my colleagues and I are deeply grateful for this gesture of friendship and for the Association's support of the high ideals for which our College stands.
>
> Yours very sincerely,
>
> ALFRED WEBB-JOHNSON.

Council Meeting

At a meeting of the Council of the College, held on May 10, with the President in the chair, Dr. R. A. Willis, who had arrived from Melbourne, was admitted as the first Sir William H. Collins Professor of Human and Comparative Pathology. The Hallett Prize was awarded to William Burnett, of the University of Aberdeen. The British Association of Urological Surgeons was added to the list of those specialist associations who enjoy the facilities of the joint secretariat at 45, Lincoln's Inn Fields.

Diplomas of Membership were granted to the 139 successful candidates whose names were published in the report of the meeting of the Royal College of Physicians of London in the *Journal* of May 5 (p. 647).

Diplomas in Medical Radiodiagnosis and in Medical Radiotherapy were granted jointly with the Royal College of Physicians of London to J. A. Ireland and L. M. Shorvon respectively.

Lister Medal

The Lister Medal for 1945, which is awarded in recognition of distinguished contributions to surgical science, has been granted to Sir Howard W. Florey, F.R.S., of the University of Oxford, for the outstanding importance to surgical science of his work on penicillin and its application. He will deliver the Lister Memorial Lecture later in 1945. This is the eighth occasion of the award, which is made by a committee representative of the Royal Society, the Royal College of Surgeons of England, the Royal College of Surgeons in Ireland, the University of Edinburgh, and the University of Glasgow.

UNIVERSITY OF GLASGOW

The King, on the recommendation of the Secretary of State for Scotland, has appointed Prof. William James Hamilton, M.D., D.Sc., to the Regius Chair of Anatomy at Glasgow University. After a distinguished career at Queen's University, Belfast, Prof. Hamilton went to Glasgow in 1930 as demonstrator of anatomy, and two years later was appointed lecturer. In 1935 he became lecturer at St. Thomas's Hospital Medical School, and since 1936 has held the Chair of Anatomy in the University of London tenable at St. Bartholomew's Hospital Medical College.

The Services

CASUALTIES IN THE MEDICAL SERVICES

Died.—Capt. James Alexander Harper, R.A.M.C.; War Subs. Capt. Clarence Wilfred O'Donoghue, R.A.M.C.

Missing, presumed killed.—Temp. Surg. Lieut. John Nairn Lennox, R.N.V.R.

Died of wounds.—War Subs. Capt. Thomas Joseph Seavers, R.A.M.C.

Medical Notes in Parliament

Alien Doctors

Answering Sir Walter Smiles on May 11, Mr. HERBER MORRISON reported that some of the foreign doctors admitte temporarily to this country had already returned. Others wer preparing to leave. He said the remainder still render valuabl service in this country, where, for the time being, there was a extreme shortage of medical man-power.

Sir WALTER SMILES suggested that, as numbers of Britis medical students had been sent to work in Europe, the Ministe should consider returning some foreign doctors to their nativ countries.

Control of Flies on Sewage Filter

On May 11 Sir JOHN MELLOR asked what reports th Minister of Health had received concerning the nuisance fro flies in the sewage filter beds of the Birmingham Tame and Re District Drainage Board. Mr. WILLINK replied that the mo recent report from the Drainage Board, received a little ove a week ago, was that the flies were not more numerous tha in recent years, though their emergence appeared to have bee accelerated by an early spell of warm weather. A group experts formed under the Department of Scientific and Indu trial Research in 1943 had directed extensive observations bo at the Drainage Board's works at Minworth and at a numb of other sewage disposal works. Much detailed informatic had been collected on the distribution and life history of fli in percolating filters and on their reaction to variations in suc factors as the composition and temperature of the settled sewa and the alternation of periods of operation and rest of t filters. Further investigation was in progress on the contr of the emergence of flies by chemical substances, and on alter tions in the construction and method of operation of filte The effect of treating the sewage at a greatly increased rate percolating filters was also being investigated. Measures we applied by the Drainage Board from time to time to allevia the conditions, including treatment of the sewage by gas liqu by salt, and by a number of chemicals, a large-scale applicati of bleaching powder and creosote, and an attempt to trap t flies by mechanical means. The problem was difficult, large because the larvae of the flies constituted an important eleme in the efficient operation of the filters. Control must therefo be restricted to the emergence of the adult flies without destro ing the biological life within the filters.

Poliomyelitis in the Army

On May 15 Sir JAMES GRIGG, replying to Mr. Rhys Davi said that the incidence of infantile paralysis in the Army sin the beginning of the war had not yet been worked out. T incidence of this disease was low, and from the general ma power viewpoint insignificant. Current statistics were not the fore maintained, and it would not be justifiable at present divert the limited statistical staff from more important wo to have this incidence worked out. It was, however, hop that details would eventually be published in the *Medical H tory of the War*. As the disease occurred in small spora outbreaks, and as the source and transmission of the vi were not yet known, it was not possible to say to what ext special preventive measures employed were responsible for cessation of an outbreak compared with, for example, natu or climatic conditions. No remedy for the disease as such known. The damage to the nerve cells attacked by the vi occurred at once and was irremediable. Once the infect process had been arrested, however, a very great deal co be done by physiotherapy and by orthopaedic surgery to educate partially affected muscles or muscles which deteriorated through inactivity. During the acute period i lungs were used to replace damaged respiratory muscles.

Tuberculosis Waiting List in Scotland

On May 15 Mr. MCINTYRE asked the Secretary of State Scotland how many patients suffering from pulmonary tub culosis were at present awaiting beds in hospitals in Scotl as a whole, and in Glasgow, respectively; and what steps proposed to take to bring an immediate end to this situati Mr. JOHNSTON in reply said that at March 31, 1945, 1, persons in Scotland suffering from pulmonary tuberculosis w awaiting admission to hospital. Of this number 1.142 were Glasgow. The Department had provided 758 beds from Government's Emergency Hospital Scheme, and the num of patients undergoing hospital treatment for pulmonary tu culosis in Scotland had already been increased by over 6 since the war began. Further beds could be made availa but there was a serious shortage of nursing staff and there w obvious difficulties in compulsorily directing girls to the serv

On this problem he was in constant touch with the Minister of Labour, and he hoped that this question and answer would draw public attention to the desirability of more volunteers being rapidly forthcoming for the nursing of tuberculous patients.

Availability of Penicillin

On May 15 Mr. SALT asked the Lord President of the Council whether he was aware that penicillin was now on sale at every drug store in the U.S.A. and was advertised for sale there as freely as cosmetics; and what steps it was proposed to take o ensure that in the early future facilities were provided in Great Britain for at least the partial development of British discoveries and inventions such as penicillin. Sir JOHN ANDERSON: It will be part of the responsibilities of the Department of Scientific and Industrial Research in the future o keep watch, with the help of other Departments, in specialzed fields such as medicine for promising results of British research which merit development in the national interest, and where such development appears to be lagging behind appropriate steps will be taken for its encouragement.

Mr. LEVY asked if the manufacture of this product was a monopoly in this country. Sir JOHN ANDERSON replied that he did not think there was any monopoly in the matter.

Deaths after Vaccination in Scotland.—Mr. JOHNSTON, replying to Mr. Viant on May 8, said that according to the records of the Registrar-General for Scotland two deaths were registered in 1943 as attributable to consequences of vaccination, the causes of death being post-vaccinal encephalitis and post-vaccinal myelitis, and the ges at death were 15 and 51 years respectively.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week there was a general fall in the incidence of infectious diseases as follows: measles 2,884 fewer cases, whooping-cough 140, scarlet fever 75, diphtheria 0, dysentery 17.

Durham had 15 fewer cases of diphtheria, Glamorganshire 5, and Lancashire 14. In Lancashire notifications of whooping-cough fell by 37 and of scarlet fever by 58. The measles epidemic is subsiding in most areas of the country, and notifications were lower than last week by the following figures: Yorks West Riding 616, Surrey 264, Essex 263, London 243, Middlesex 202; there were increases of 189 in Kent, 79 in Cornwall, and 76 in Southampton.

For the second successive week there was a small decrease in the incidence of dysentery. The largest returns were Lancashire 54, London 51, Warwickshire 45, Gloucestershire 31, Kent 7, Hertfordshire 24, Yorks West Riding 21, Pembrokeshire 0, Staffordshire 20, Middlesex 17, Essex 14, Shropshire 14, Devonshire 12, Norfolk 11, Northumberland 11.

In *Scotland* whooping-cough notifications fell by 52 cases, those of diphtheria by 33, and those of dysentery by 15, while those for cerebrospinal fever increased by 12. Diphtheria is low at the lowest level for several months. Dysentery is still revalent, the largest returns being Glasgow 51, Edinburgh 39, Aberdeen Burgh 19, Dundee 11, Falkirk 10, Aberdeen County 10.

In *Eire* there was a fall of 31 in the notifications of diphtheria; 21 of the 73 cases were reported from Dublin C.B., and the other 52 involved thirty areas.

In *Northern Ireland* only 8 cases of diphtheria, a fall of 14, were notified. An increase of 16 was recorded for scarlet fever.

Scottish Vital Statistics

The preliminary review of the first quarter of 1945 shows a large fall in the birth rate, which was 16.9 per 1,000, the lowest ver recorded for a first quarter. The infant mortality was 68 per 1,000 births, and was the lowest rate for the first quarter of any year. The death rate, 14.6 per 1,000, was 0.7 above the rate for the corresponding quarter of 1944, but 1.9 below the five-years average. The marriage rate, 7.6 per 1,000, was .6 above the rate for the March quarter of 1944.

Typhus in P.O.W.

There are 8 or 10 cases of typhus or suspected typhus among prisoners of war returned to this country. The disease was contracted in Germany, and there have been no secondary cases. In any case of pyrexia of unknown origin practitioners should bear in mind the possibility of typhus.

Week Ending May 12

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,365; whooping-cough 99, diphtheria 413, measles 12,412, acute pneumonia 511, dysentery 343, paratyphoid 3, typhoid 4.

No. 18

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended May 5.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

Stillbirths	190	11	35			234	26	32		
Rate per 1,000 total births (including stillborn)			39					31		

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

The St. Cyres Lecture for 1945 will be delivered in the Barnes Hall of the Royal Society of Medicine (1, Wimpole Street, W.), on Wednesday, June 6, at 5 p.m., by Prof. J. Crighton Bramwell. His subject is "Coarctation of the Aorta." All members of the medical profession are invited to attend.

A general meeting of the Medical Society for the Study of Venereal Diseases will be held at 11, Chandos Street, W., to-day (Saturday, May 26), at 2.30 p.m., when "Treatment of Infective Arthritis, with Special Reference to Hyperthermia" will be discussed by Lieut.-Col. A. J. King and Majors C. S. Nicol, D. I. Williams, and J. Louden.

The meeting of the Nutrition Society to be held to-day (Saturday, May 26) at the London School of Hygiene and Tropical Medicine will be devoted to nutritional factors in wound healing. The chairman of the morning session will be Prof. H. P. Himsworth, and of the afternoon session Prof. J. R. Learmonth. Dr. D. P. Cuthbertson will open the discussion at 12 noon with a paper on dietary protein in relation to convalescence from injury. In the afternoon papers will be read on vitamin C and wound healing, the speakers including Drs. J. F. Danielli, H. B. Fell, E. Kodicek, P. D. F. Murray, and Geoffrey H. Bourne. Non-members are admitted to meetings of the society only by introduction of a member.

Mr. Eardley Holland's Chadwick Lecture on "The Importance of a Maternity Service in the Life of the Nation" (postponed from May 8) is to be delivered on Tuesday, May 29, at the Royal Society of Tropical Medicine and Hygiene, 26, Portland Place, W. Immediately before the lecture (at 2.15 p.m.) the Chadwick Prize of £100 and a gold medal is to be presented by the chairman of the Chadwick Trustees, Sir William J. Collins, to Surg. Capt. S. G. Rainsford, M.D., D.Sc., R.N., who will be introduced by the Medical Director-General of the Navy. Admission to all Chadwick Lectures is free, without ticket.

A meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine will be held at the R.A.F. Station, Halton, Bucks, on Friday, June 1, at 3 p.m., when an introductory address will be given by Air Marshal Sir Harold Whittingham, Director-General of Medical Services of the R.A.F. On the same day the combined summer meeting of the Sections of Laryngology and of Otology will begin at 1, Wimpole Street, W., at 10.30 a.m., with a demonstration of R.A.F. hearing tests for use in the selection of flying personnel. Papers will be read in the afternoon, from 2.30 p.m., and the combined meeting will continue its business on Saturday, June 2.

The Socialist Medical Association has arranged a meeting to be held at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C., on Saturday, June 2, at 3 p.m., when Prof. J. A. Ryle will speak on "Health Problems of British India."

Lord Moran, P.R.C.P., will give an address on "Courage and Fear" before the Royal Institution (21, Albemarle Street, W.) on Friday, June 8, at 5 p.m.

The Association of Industrial Medical Officers has arranged a meeting at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C., on Saturday, June 9, at 2 p.m., when private business will be discussed. At 2.30 p.m. Mr. S. H. Wilkes will speak on "Protection against Industrial Poisoning."

The January issue of the *Annals of Internal Medicine* is devoted to the epidemiology of acute respiratory infections conditioned by sulphonamides. The March issue of the *Journal of Pediatrics* contains a symposium on rheumatic fever.

Boots Pure Drug Company Limited announce that Sir Jack Drummond, D.Sc., F.R.S., chief scientific adviser to the Ministry of Food, has been appointed to the post of director in charge of the whole of the company's scientific research. Sir Jack Drummond has resigned the chair of biochemistry at University College, London, but will not take up his new appointment until the food situation has improved.

The freedom of the borough of Paddington was conferred last week on Sir Alexander Fleming, F.R.S., as a token of the high esteem in which he is held by the civic authority of the borough where he has carried out, at St. Mary's Hospital, his scientific researches and in which his discovery of penicillin was made.

From Dr. Ralph Pemberton, President of the Pan-American League against Rheumatism, Lord Horder has received a letter congratulating the Empire Rheumatism Council on the decision of the British Government to make, in post-war health policy, adequate provision for the treatment of rheumatic sufferers. Dr. Pemberton adds, "This will influence thought everywhere."

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to TH EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUAR LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiolog Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded f publication are understood to be offered to the *British Medical Journal* alon unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishin Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proof Authors over-seas should indicate on MSS. if reprints are required, as proo are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manage B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m. TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

ANY QUESTIONS?

Lead Palsy

Q.—*Is there any explanation of the fact that the supinator longu muscle is not involved in radial nerve paralysis due to lead poisoning? Also, why are sensory nerve changes uncommon in this typ of poisoning?*

A.—The explanation is that the lesion in lead palsy is not in th peripheral nerve. Aub and his collaborators showed that the lacti acid liberated in muscles by their contraction leads in the presenc of lead phosphate to the precipitation of insoluble lead phosphate i the muscle cells, and selective muscular paralysis has been experimentally produced by fatiguing certain muscles. The conditio therefore is a toxic myopathy. In painters the extensors of th wrists and fingers, being most used, suffer most, and the supinato longus escapes.

Micturition

Q.—*In the erect posture the internal urethral orifice is situate in the most dependent part of the bladder. How can this be reconciled with the fact that in haematuria of bladder origin and i phosphaturia it is the urine which is passed at the end of micturitio which is most heavily blood-stained and most heavily laden wit phosphates respectively? One would expect deposits of blood o phosphates to be passed with the first fraction of urine voided. Wh is the explanation?*

A.—The probable though unproved explanation is as follows. A the bladder fills the base behind the inter-ureteric bar sinks an becomes the lowest part of the viscus; in this region, and partic larly to right and left of the middle line, debris tends to accumulat On micturition it is obvious that the urine most adjacent to th internal meatus is the first to be expelled. If a bladder is watch through a flushing cystoscope whilst it is being allowed to drain, will be seen that the superior part descends, the wall becomin convex into the cavity during this process. Thus the cavity gradually obliterated from above downwards—though of cour local contracture towards the mid-point also occurs. This mi point is the internal meatus, and when the bladder is almost emp the form of the cavity may be compared to the letter T, but o with the cross not horizontal. The stem represents the prostat urethra; the anterior part of the cross is the bladder lumen anteri to the meatus, and this is turned upwards; the posterior part of it the retromeatal region, and this is turned downwards. On cyst scopy the adjacent part of the bladder cavity lying behind the inte ureteric bar can be seen to be the last to empty. Stasis of contents may also be due to special fluid currents set up duri micturition, but so far as is known these have not been demonstrate

Erythrocytosis in Disease

Q.—*Erythrocytosis is said to occur in certain types of visce syphilis, and occasionally in pituitary basophilism. What is t explanation in each of these two disease processes?*

A.—Erythrocytosis has been described in a number of conditio in which there is enlargement of the liver and/or spleen—e. cirrhosis of the liver, tuberculosis of the spleen, and lymphadenom and visceral syphilis should probably be included in this group. T mechanism responsible for the erythrocytosis is not known, thou it is noteworthy that clubbing of the fingers may also occur. T explanation of erythrocytosis in pituitary basophilism is al unknown, and it has not been possible to reproduce the condition experimental animals.

Urticaria Again

Q.—*Are peptone injections of use in the treatment of urticaria?*

A.—Urticaria is usually considered nowadays to be an allerg manifestation due to a sensitivity on the part of the sufferer various drugs (aspirin, phenolphthalein, sulphonamides), enviro nental articles (feathers, dusts, animal hairs, powders, oils), foods r physical agents (heat, cold, light, friction). Formerly it was only onsidered due to a sensitivity to foods of protein origin, and when ood skin tests and dietary experiment and eliminations did not mprove the disorder, a protein product (peptone) was chosen for njection and given in increasing doses with the hope that it would ring about a non-specific desensitization. Now that the greater mportance of drugs, feathers, dust, animals, and physical agents s realized, their avoidance and specific desensitization offer a greater ope of cure.

Filtering Entamoeba histolytica from Water

Q.—*What type of filtration will remove cysts of Entamoeba istolytica from water?*

A.—I find this question a little difficult to answer. There is the ossibility that the questioner may be referring to the removal of ysts of *Entamoeba histolytica* either on a large scale, such as for ater supply, or on a personal or domestic scale. If the former, ny of the standard processes used for purification of water supplies, uch as sand filters worked at the rate of four inches per hour, the nore rapid mechanical filters, in which sulphate of alumina is used, r the Candy type of filter, would all be an efficient means of preenting the passage of cysts of *Entamoeba histolytica*. On the omestic scale any of the small filters, the basis of which is the use f infusorial earths, clays, porcelain, or combinations of porcelain ith clay, would be equally efficient. The efficiency of all these lters is mainly dependent on the pore size of the filtering material, nd the comparatively large size (5–20μ) of the cysts of *Entamoeba istolytica* makes it impossible for them to traverse an efficiently orking filter of any type.

Treatment of Inevitable Abortion

Q.—*What, in your opinion, is the best treatment for an inevitable bortion? I am frequently called to such cases and usually find an complete abortion with a very fair haemorrhage. Do you advise ttempting digital removal of the remains before sending to hospital r dilatation and curettage? Do you advise giving pituitary to these ses before removal of the debris?*

A.—For the uncomplicated case, put the patient to bed, protect e vulva with a sterile pad, give morphine or omnopon—partly to lieve pain and partly to allay anxiety—and allow the abortion to roceed without any local interference. The only indications for tive intervention are: (*a*) excessive bleeding, (*b*) infection, or) retention of part of the products of conception. In the last stance, and particularly if the whole placenta is retained, there is need for immediate exploration of the uterus unless haemorrhage r pyrexia supervenes. In the absence of such it is safe to wait ne or two days in the hope of spontaneous expulsion. During that ne pituitary extracts may be administered without risk—as they ay during the process of complete abortion or during operation r incomplete abortion. Oxytocin (5 units intramuscularly) is rhaps preferable to pituitrin.

Complete removal of all retained products of conception with y degree of certainty and safety requires digital exploration of the erus, the patient being anaesthetized and under hospital conditions. o carry out what would probably be a partial removal, before ansferring the patient, only increases the risk of infection and puts e patient to unnecessary discomfort; it is not very likely to allay eeding and might even increase it. Even vaginal examination ould be avoided if possible. It should be added that when the tient is exsanguinated and shocked blood or plasma transfusion ould be carried out before she is sent to hospital. Indeed the more serious cases of haemorrhage the whole treatment, cluding digital evacuation of the uterus, is probably best carried it without moving the patient from her home, but expert assistance d suitable equipment should be available.

Fibrous Nodules in Arthritis

Q.—*A patient with rheumatoid arthritis has several fibrous nodules the gluteal muscles. They are from 1/2 to 3/4 in. in diameter. ey are not tender in themselves but evidently transmit pressure to nder subjacent structures when the patient is in the sitting position. ft rubber pads strapped to the skin cause some relief but are fficult to keep in place. What treatment is recommended, and is y form of physiotherapy likely to be of use?*

A.—Fibrous nodules in the gluteal muscles are not common in eumatoid arthritis and are difficult to deal with; surgical removal worth consideration but is often difficult, and fresh nodules may pear in the same situations. It is most important to relieve essure and at the same time very difficult. I have not found any ysiotherapeutic methods helpful. Injection of iodolysin is somenes followed by disappearance of nodules in other parts, and a al would be justified. The injections should be made into the teal muscles in the vicinity of the nodules, with no attempt to nsfix them. After a few injections a long course of the same nedy should be given by mouth, with occasional intervals.

Vitamin B_1 for Neuritis

Q.—*Intensive treatment with vitamin B_1 is recommended for neuritis. Is it possible to do harm by excessive doses? What is the normal and what the maximum dosage?*

A.—It is doubtful if vitamin B_1 therapy is any more effective in the treatment of neuritis than the usual remedies, such as rest and physiotherapy, unless, of course, there is an underlying deficiency of vitamin B_1. It is possible to do harm by excessive doses. There is a delicate equilibrium between the metabolism of the B vitamins, and a massive dose of one has been observed to precipitate symptoms of a deficiency of one or more of the others. This was noted in 1941 by Sydenstricker (*Ann. intern. Med.*, 1941, **14**, 1499) and has been repeatedly confirmed. Large doses of vitamin B_1—e.g., 25 to 75 mg. a day parenterally—are recommended at first, and when the desired relief is obtained, maintenance doses of 3 mg. t.d.s. by mouth are given. Up to 100 mg. can usually be given in a single dose with safety, although in a few susceptible patients toxic effects with such dosage have been reported. If there is no improvement in a few days it is useless to continue treatment. Some source of the other B vitamins, such as brewers' yeast or wheat germ, should be prescribed as well if large doses of vitamin B_1 are given.

Addition of Sodium Citrate to Milk

Q.—*Sodium citrate is much used in treating babies and young infants to reduce the size of milk clots during digestion and in larger dose in urinary conditions. Is there any danger of alkalosis developing? If so, what are the maximum safe doses for (a) short and (b) long-continued treatment?*

A.—Assuming that the baby or young infant is normal, without vomiting or diarrhoea, and that sodium citrate is being added to the milk in the proportion of 1 to 2 grains for every ounce of *whole* milk, then there is no danger of alkalosis. (If the milk is boiled, as it should be, the addition of citrate makes very little further difference to the size of the clot or to digestibility, and is really no longer as useful a method as it was once thought to be.) In the treatment of urinary conditions there is certainly a danger of alkalosis—especially if sickness and diarrhoea are present. The value of alkaline administration in urinary infections lies almost entirely in producing a sudden change from an acid to an alkaline reaction in the urine. For this purpose, the usual adult dose of 30–60 grains of citrate two-hourly until the urine is alkaline, and then four-hourly for another 48 hours, can be adapted to a child's weight: i.e., a 7-lb. newborn baby gets 1/20 of a 10-stone adult's dose; an infant of 6 months gets 1/10 adult dose; and so on. On this short and sharp regime the danger of alkalosis is small.

Long-continued use of alkalis has surely now been replaced by sulphonamide treatment, and the last part of the question does not really arise. If big doses *are* used for more than a few days, the plasma bicarbonate should be estimated. It should be remembered that citrates act precisely as carbonates or bicarbonates in the tissues, and are therefore just as likely to cause alkalosis. Their merit is that they do not neutralize gastric juice and are said, therefore, not to produce as much digestive upset. If free diuresis occurs with citrate therapy, as it should, there is a risk of chloride loss, which predisposes towards alkalosis. Long-continued use of citrates should, therefore, be accompanied by a daily dose of sodium chloride—again based upon an adult dose of 120 to 240 grains daily.

INCOME TAX

Storage of Car during Active Service

R. M. ceased civil practice on joining the Forces. Circumstances have required him to lay up his car (so that it may be available for professional use after demobilization) at a cost of £12 a year. Can he claim any deduction for that expense?

*** The Income Tax Acts do not provide any *general* provision for the allowance of expenses; they proceed by defining certain classes of income liable to tax and then providing for the deduction of expenses in assessing the incomes. Thus deductions are permitted for repairs in the Schedule dealing with income from property, for necessary expenses in Schedule E, for ordinary current expenses in Schedule D, etc. R. M. is in this difficulty—the £12 a year expenditure is not incurred in connexion with any income for *which he is assessed*; it is incurred to keep in stock, so to speak, an asset for use in the future. We are not aware of any provision in the statutes on which he can base a claim to have it treated as a subject for allowance against the tax he suffers on his official pay or on any other income he may have. He has a right of appeal against the assessment of tax on his pay, which he can exercise by giving notice to the War Office Assessor of his wish to do so. But it seems to us hopeless to contend that the £12 in question is expended wholly, exclusively, and necessarily in performance of his duties as an officer in the R.A.M.C., and that is the proposition he would have to substantiate. (In the case quoted by R. M. the owner of the car was continuing to carry on his civil practice.)

LETTERS, NOTES, ETC.

Unilateral Flush after Food

Dr. F. PARKES WEBER (London, W.1) writes: The case so interestingly discussed under the above heading among "Any Questions?" (May 12, p. 687) resembles the "auriculo-temporal syndrome," except for its extreme mildness and for the fact that it is not connected with scarring in the parotid region. In fully developed examples of the auriculo-temporal syndrome the flushing at the side of the face on eating is accompanied by local sweating. The exact mechanism of the autonomic nervous disturbance which causes the remarkable flushing and sweating on eating is not absolutely certain, but apparently in cases like the one under discussion there is some *developmental* peculiarity in the local autonomic nervous apparatus which causes a disturbance similar to, but less severe than, that caused by the parotid scars in true cases of the auriculo-temporal syndrome (F. P. Weber, *Med. Pr.*, 1944, **211**, 199).

Musculospiral Palsy

Mr. A. R. PARKES, F.R.C.S.Ed. (Glasgow) writes: In the issue of April 14 there is a paragraph entitled "Musculospiral Palsy." Surely the answer to the question is that the patient would seem to have had a partial lesion of the *ulnar* nerve, probably a transient physiological block. The symptoms described are far more consistent with interruption of conduction in the ulnar nerve than in the radial. Moreover, it is more common to get pressure on the ulnar nerve (in the forearm) than on the radial when sitting in a deck chair.

*** Our adviser writes: It is true that an ulnar palsy causes semiflexion of the ring and index fingers, but the patient with an ulnar palsy does not usually complain that these fingers "get in his way," because there is hyperextension at the metacarpo-phalangeal joints. In the case reported the patient also complained that he could not strop his "cut-throat" razor because "he could not turn it over"—i.e., supination of his forearm was also weak. The supinators are supplied by the musculospiral, and only a musculospiral lesion could cause weakness of supination and inability to extend the ring and little fingers.

Portraits of William Harvey

Mr. WILSON STEEL, Sub-Librarian, University of Glasgow, writes: My attention has just been drawn to the article in your issue of Nov. 18, 1944 (p. 669), in which Mr. Geoffrey Keynes deals with the portraits of William Harvey. May I point out, a little late in the day perhaps, two matters of fact upon which Mr. Keynes has gone wrong. Talking of the portrait in the Hunterian Collection in the University of Glasgow he says that the landscape background contains "many buildings, the two most conspicuous of which can be identified as probably the dome of the old College of Physicians and Trajan's Column," and adds that the Roman association has "no particular relevance to Harvey." In point of fact the background of the portrait is simply a view of Rome and not a composite landscape dictated by the artist's fancy. The dome adjacent to Trajan's column is easily identifiable as belonging to the Church of S. Maria di Loreto and not as that of Wren's old College of Physicians, to which it has not the faintest resemblance. In the matter of relevance we learn from the *Dictionary of National Biography* that Harvey visited Rome in 1636 and dined at the English College on Oct. 5 of that year.

Diet and Dental Health

Dr. A. LIVINGSTONE (Southampton) writes: I have read with the greatest interest recent articles in your journal and in others which at first sight "debunk" the value of vitamin C in preventing or curing gingivitis. In *Nature* for June 17, 1944, there is a letter pointing out the essential need for manganese in the diet so that the body may make or utilize (or both) vitamin C. This leads me to observe that, as has so often been pointed out, our grandmothers were right; when their dentures gave them sore mouths they sucked a lump of alum, preferably "iron alum," from the ironmonger's. ("Iron alum"—Potassium ferric sulphate. Pale violet crystals, efflorescent in dry air. *Practical Chemistry*, Bruce and Harper, London, 1911.) These alums probably contained traces of manganese as an impurity (*Pharmacopeia*, White and Humphrey, London, 1909). Ingestion may have enabled the old ladies' digestive tract, especially in the region of the jejunum, to make or utilize vitamin C; the sore mouth was really subliminal scurvy. Further, there appears now to be a distinct cycle of events. Boils and "colds on the lip" are, certainly in this neighbourhood, becoming very frequent. The shortage of fruit and consequently of vitamin C, the shortage of potassium and manganese in crops grown on soil old and tired and certainly short of these elements, are leading to a sugar intolerance, the pancreas being disturbed through lack of vitamin C. Tooth structure is affected as shown by caries rapida. No attention appears to have been paid to the tooth pastes used by the Forces. Some considerable clinical experience, borne out by others of my profession, shows that the tooth pastes containing "ricinoleate" in very many cases profoundly irritate the gum margins: in many cases they appear to cause an allergy. I have been informed by a senior officer of the W.R.N.S. that the only tooth paste that was available in the nearest canteen for some time contained "ricinoleate," and practically every one of the girls had inflamed and bleeding-gums, which did not respond to treatment with vitamin C There is also a clinical slow deterioration in the normal condition of the gums after the long-continued use of tooth pastes containing borates and perborates. I understand that boric acid inhibits the growth of cells and tissues, and it is forbidden to add it as a preservative to foodstuffs. In tooth pastes it appears to lead to failure to replace the epithelium of the gums, which become excessively thin and bleed on the slightest touch; even chewing food will cause haemorrhage, as in serious cases where "ricinoleates" are used. Would it not be possible for the Ministry of Health to issue a formula for common table salt containing a sufficient supplement of the trace elements? Lastly, the following is a formula for a tooth powder which gives traces of potassium if not rinsed away after the surplus has been spat out: sod. bicarb. ʒij; calc. carb praecip. ʒij, pot. chlorate ʒij, sod. chloride ʒij, ol. limonis m x I am much obliged to Mr. Graham Clift for helping to run the "iron alum" to earth.

A Prolonged Case of Pulmonary Tuberculosis

Dr. JOHN J. LAWS writes: Pulmonary tuberculosis is notoriously variable in its course. While many cases terminate fatally after a longer or shorter period, others are more chronic; and still others heal with fibrosis, leaving scars still visible at necropsy many years after. Even the most chronic cases, however, tend to go one way or the other in course of time, so that it may be of interest to give some account of a case in which the disease still showed mild activity when the patient died of senile changes at 90, it having been present for at least 24 years, and probably more than twice tha time. The patient entered a mental hospital at the age of 66, suffering from persecutory delusions. These did not markedly affect hi general conduct, and he was able to lead a fairly reasonable institution life, often in parole villas. He had—on admission—a histor of having had treatment for pulmonary tuberculosis in different hospitals for many years. One of his chief symptoms had been intermittent haemorrhages—the first 30 years before. So that one can probably assume an age of onset somewhere between 35 and 40 His story after admission was very similar to that before: occasional bouts of cough and pyrexia, and haemoptyses at irregular intervals These, though never very copious, were usually severe enough to warrant a period of rest in bed. Physical examination revealed signs of a chronic right-sided lung lesion. At no time were tubercle bacilli found in his sputum, though search was frequently made X-ray examinations during his 16th and 22nd years in hospital confirmed in general the physical findings—"Fibroid tubercle bot apices—especially right." At post-mortem there was a small are of fibrosis at the right apex containing several small cavities—none larger than a small bean. At the base of the right middle lobe there was a slightly more active lesion—one or two cavities fille with stiff caseous material. A further small fibroid lesion was present at the left apex. No other tuberculous lesions were found; but th heart and kidneys showed marked arteriosclerotic changes, the latte especially being very shrunken and contracted. Microscopic examination of sections from the most active-looking pulmonar lesions showed a typical tuberculous reaction, with giant cells and scattered acid-fast bacilli. I wish to thank Dr. F. G. L. Barne medical superintendent of Long Grove Hospital, Epsom, for permi sion to publish this case.

Epilepsy and Menstruation

Surg. Cmdr. H. LOVELL HOFFMAN, R.N.V.R., writes: I note that th induction of an artificial menopause in so-called "menstrual epilepsy was recently mentioned in the *Journal* ("Any Questions?" March 1 p. 396). I have no detailed notes, but I remember one of n patients who was so treated. This woman assured me that she never experienced fits except in association with menstruation. She ha always been free of attacks during her pregnancies. As she wa aged about 34 and had several children it was decided, after consultation with a gynaecologist, that the production of an artifici menopause was justified and this was carried out with radium. Th periods stopped and so did the fits, the patient being delighted wi the result. Some months later she informed me that she had ha but one slight seizure while mildly intoxicated at Christmas! Th menopause was not permanent, and both periods and fits gradual returned. As I left the hospital shortly afterwards I unfortunate lost touch with the patient. In many women fits occur more ofte just before or just after menstruation, but there are also attacks other times. It is rare to see a case, such as that quoted, in which fits occur only in association with the periods. If the relationsh is less definite or other obvious factors, such as age and number of children, are not so favourable, I doubt if this method of treatment is justified.

CLINICAL FEATURES OF THE POLIOMYELITIS EPIDEMIC IN MALTA, 1942-3

BY

T. AGIUS, M.D., D.C.H., M.R.C.P.   A. E. BARTOLO, M.D.   C. COLEIRO, M.D., D.P.H.

AND

H. J. SEDDON, D.M., F.R.C.S.

In Nov., 1942, when the siege of the islands had just been raised, Malta and its small neighbour Gozo were still further stricken by a serious outbreak of poliomyelitis, the first of any note in their history. Between Nov. 15, 1942, and the first week in June, 1943, there were 426 cases in the civilian population, almost all in children under the age of 5 years (Fig. 1).

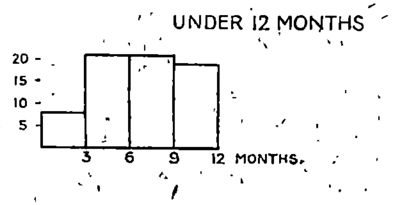

FIG. 1.—Diagram showing the age incidence of cases.

At the same time 57 Service cases occurred, the victims being without exception men from the United Kingdom. The epidemiology of the outbreak has been discussed elsewhere by Seddon, Agius, Bernstein, and Tunbridge (1945). Bernstein, Clark, and Tunbridge describe the clinical features of the Service cases in this issue, at p. 727; the present paper is concerned with those of the civilian outbreak.

The occurrence of such an epidemic in a community where conditions are otherwise normal is no light matter. In a small island that had been subjected to prolonged and ferocious aerial bombardment, and that had hardly recovered from a food shortage verging on famine, the provision of adequate accommodation and treatment for over 400 cases of poliomyelitis was a task requiring exceptional resourcefulness and determination. Satisfactory accommodation was found within a remarkably short time in the new but uncompleted Government hospital (now known as St. Luke's), though for several months there was a shortage of equipment and of physiotherapists. Improvised wooden splints for the legs and calico slings for the arms were applied under the direction of Prof. E. Debono, and the supervision of these small children was so strict that a complete review of all cases made in March and April, 1943, revealed only two in which there was very slight contracture. While the epidemic was in progress there was insufficient time for taking detailed histories of onset; furthermore, at that time many of the mothers were so distraught that it was impossible to obtain coherent stories from them. During February and March, when the state of emergency was coming to an end, one of us obtained detailed histories of onset in all except a very few cases. This information, together with the shorter notes made at the time of admission, gives a fairly clear picture of events during the active phase of the disease. In the spring of 1943 all but five of the survivors were re-examined and the muscle power charted according to the system of notation recommended by the Peripheral Nerve Injuries Committee of the Medical Research Council. This work was most laborious. In older children accurate muscle examination requires time and patience; in infants it is exceedingly tedious, and the results cannot always be regarded as strictly accurate. In every case of doubt a low rather than a high grading was given, and it may well be that the effects of this epidemic will prove less serious than the original forecast suggests. By early March, 1943, only 160 children were in hospital; in the case of out-patients living in towns remote from St. Luke's Hospital the detailed examinations were made at district dispensaries and, as a last resort, in the homes of patients whose parents lacked the means or the inclination to bring their children to a clinic. Under such conditions accurate work was not always possible.

Clinical Features of the Acute Disease

Onset

In some cases the illness was so mild that during the acute phase the child was not put to bed at all; indeed, the symptoms were often so vague that the disease was completely overlooked. In others it was mistaken for some other condition such as paralytic chorea, diphtheria, or meningitis. However, close questioning usually elicited a history of some general disturbance. In a few cases the onset was very acute, with convulsions that seemed to threaten life; it is probable that this was the state of affairs in the case of three patients who died at home. The duration of the acute illness varied between 1 and 17 days, though in most cases the general disturbance lasted for not more than four days. The detailed figures are as follows:

In 59 cases	duration 1 day	In 9 cases	duration 8 days
„ 73 „	„ 2 days	„ 5 „	„ 9 „
„ 55 „	„ 3 „	„ 9 „	„ 10 „
„ 46 „	„ 4 „	„ 1 „	„ 11 „
„ 18 „	„ 5 „	„ 4 „	„ 12 „
„ 16 „	„ 6 „	„ 1 „	„ 13 „
„ 17 „	„ 7 „	„ 8 „	„ 14–17 days

In 10 cases there was no systemic disturbance.

Fever

Out of 396 cases 245 were pyrexial at some time during their illness, there being low fever (below 101°) in 159 and high fever (above 101°) in 86 cases. Rigors were observed in 18 cases. It is probable that fever was present in a greater number than is indicated by these figures, but our information is incomplete. The duration of fever varied; in 159 cases it lasted for not more

4404

than 24 hours, which leads us to suspect that it passed unnoticed in many more. In 56 cases the duration was 2–3 days; 7 cases, 3–4 days; 11 cases, 4–5 days; 12 cases, more than 6 days. Twenty children were afebrile throughout. In a few cases the febrile disturbance disappeared, to reappear at about the time when paralysis developed. The febrile disturbance was present usually at the onset of the disease, though in a few it developed after the paralysis had appeared.

Pain

In view of the youth of most of the patients it is difficult to give the actual incidence of pain, and it may well be that the figures presented here are rather too low. In the very young pain manifested itself in various ways. A child would refuse to have his napkin changed, resented fondling or handling of any kind, and wished to be left alone. In several cases the child would not tolerate being bathed. In one case the mother noticed the child scratching the limb which later became paralysed; there was no local skin lesion. In two cases children complained of a pricking sensation in the limb about 48 hours before the development of paralysis.

The site of pain did not as a rule correspond with the distribution of the subsequent paralysis. For example, pain in the back was followed by facial or deltoid paralysis; pain in the face by paralysis of the lower limbs; pain in one lower limb by paralysis of an upper limb; pain in one lower limb by paralysis of both; and pain in the shoulders by facial palsy. In one case severe orbital pain was followed by paralysis of one lower limb. In another, suprasternal pain was followed by difficulty in swallowing, then by facial palsy. Headache occurred in 72 cases, and was unassociated with any particular kind of paralysis; the cases of cranial nerve palsy were usually unassociated with headache. Pain occurring in a limb which subsequently became paralysed was observed in only 28 cases.

The severity of the pain did not correspond with the extent or severity of the subsequent paralysis. Indeed, many children who complained bitterly of pain escaped with less paralysis than those who did not. In one case pain was severe for three days and nights; both lower limbs became paralysed and yet recovered completely. In a few cases the pain was recurrent and of short duration; in one it moved from limb to limb in a manner that was suggestive of acute rheumatism. On the whole pain was not an outstanding feature in this epidemic. In 96 cases the child cried intermittently as if in distress, and in 57 the crying was no more than a whine or a whimper. In 56 cases the pain was limited to one part of the body, and in 28 it appeared in the part which later became paralysed. Sixty-six children seemed to be sore all over and greatly resented handling; but this was the nearest approach to the characteristic muscle tenderness in acute poliomyelitis that was seen.

Nervous System

(*a*) *Somnolence* was noticed in 150 cases, and in some it was pronounced, the child having to be wakened for his feed, perhaps only to fall asleep again during the course of it. Many of the babies were extremely lethargic. Some children slept at unusual hours or were late in waking up. During the period of sleep or drowsiness a number of children (107) exhibited jerking movements, which were the occasion for considerable alarm. One hundred children had restless nights, though this feature corresponded fairly closely with the incidence of fever. In 6 cases there was a reversal of the sleep rhythm, the child sleeping by day and being restless at night.

(*b*) *Delirium* was noticed in only 20 cases, and occurred generally at night; 13 children had convulsions. Four children lost consciousness for periods of up to 12 hours.

(*c*) Seven children and one adult complained of *vertigo;* one child said repeatedly that he felt like a drunken man, and an adult made a similar complaint. Another child complained that the bed was spinning round, and said he felt dizzy and was going to fall; the vertigo was accompanied by vomiting. In two cases vertigo was aggravated by changing the child's position in bed or by raising the head from the pillow. In one of the cases of vertigo there was a cerebellar disturbance. One child could not tolerate street noises.

(*d*) *Stiffness of the back* was remarkably infrequent; it was observed in only 7 cases. Spasmodic contraction of muscles followed by paralysis occurred in only one case. Tremors and involuntary movements were present in 7.

(*e*) Thirty-eight patients were very *irritable,* even to the extent of throwing things at those who attended them; in 22 cases there was a noticeable change in temperament. Two patients were extremely apprehensive; one of them—the adult who died—was sure long before the end that his illness would be fatal. A rather similar fear seemed to be present in the minds of other children, who complained bitterly when left alone.

(*f*) *Loss of speech* occurred in 6 cases, in three of which there was facial palsy; one child in this group presented typical cerebellar symptoms and signs.

(*g*) *Twitching of the eyelids* was noticed in 11 cases, and strabismus in 2. One case developed bilateral ptosis. Nystagmus was not seen in any of the cases.

(*h*) *Paralysis.*—Except in the 10 cases in which there was no general disturbance it was difficult to determine the exact date of onset of the paralysis; the child was already ill, perhaps in bed, and neither the parents nor the child could say when the diminution in muscle power started. In addition to these 10 cases there were 9 in which a general disturbance followed the paralysis. In most cases the paralysis appeared fairly soon after the onset of the general disturbance; in dealing with such young children it was, unfortunately, impossible for us to be more precise. There were, however, several interesting exceptions. In 12 cases the paralysis developed a number of days after the general disturbance was over, when some children were actually going about again; in 10 the paralysis came on when the child had been up for two days, and in 2 it did not appear until after two weeks. In 13 cases there was, similarly, a general illness followed by apparently complete recovery; then there was a second period of malaise, at the end of which paralysis developed. One case was especially dramatic. A child was ill for a few days, and apparently had recovered completely; eight days later he was taken ill at 3 p.m., and 11 hours later died of respiratory paralysis. It is of course possible that the initial disturbance was not due to poliomyelitis, and it has recently been suggested that certain infections, particularly of the intestine, pave the way for entry of the virus by the alimentary portal.

In a number of cases there was an initial weakness of the limbs, which appeared to be of a temporary nature but later gave place to severe and long-standing paralysis. The weakness was revealed by unsteadiness, with frequent falls, which was often present for some time before the appearance of frank paralysis. In no instance was there an irregular spread of paralysis affecting one limb after another. In three cases the paralysis was ascending and fatal.

The results of examination of the cerebrospinal fluid will not be enumerated, as although lumbar puncture was performed on most cases admitted to hospital the information gained was of no special interest.

A number of children were vaccinated against smallpox or received injections for one reason or another a short time before the onset of poliomyelitis. The four vaccinated cases were inoculated at the usual site in the upper limb, and the subsequent paralyses were as follows: (*a*) vaccination in left upper limb—paralysis of same limb; (*b*) vaccination in left upper limb—paralysis of right upper and both lower limbs; (*c*) vaccination in left upper limb—paralysis of left lower limb; (*d*) vaccination in left upper limb—paralysis of face, left upper and lower limbs. One child was receiving intramuscular injections for whooping-cough; both upper limbs had been injected, and he developed paralysis in one. Five children were receiving antimony compounds intravenously or intramuscularly for leishmaniasis, but in no case could the site of injection be correlated with that of the subsequent paralysis. There is therefore no conclusive evidence that the virus was accidentally introduced by injection.

Alimentary and Respiratory Systems

Anorexia was almost constant, and 12 children complained particularly of thirst. Salivation unrelated to teething was noticed in 14 cases; it was not followed by one form of paralysis rather than another. Dysphagia was present in 5 cases. Vomiting occurred mainly at the onset of the illness, and was observed in 117 cases; it occurred only once in 99, twice in 11, three times in 2 cases, and repeatedly in 2 others. Late and persistent vomiting occurred in 4, retching and vomiting in 3 cases, the retching being a marked feature throughout the acute phase of the illness; retching in the absence of vomiting occurred in 4 cases. Abdominal pain without difficulty in micturition was noticed in 42 cases; it was never persistent, and was easily relieved by hot fomentations; 108 children suffered from constipation—usually obstinate and relieved with difficulty; diarrhoea was present in 5 cases, diarrhoea and tenesmus in 1 case.

An initial coryza was noticed in 80 cases, 6 children had sore throats, and in 28 a cough was present; hoarseness of the voice or cry was observed in 4 cases.

Urinary System

Several children suffered from retention of urine; in other cases the child took a long time to start or complete the act of micturition. In only one case was catheterization necessary.

None of the visceral symptoms that have been described were apparently due to local disturbances, and it was therefore not unreasonable to regard them as manifestations of the ingravescent disease; it was of interest, perhaps of importance, to determine whether symptoms referable to one particular system or body level were followed by paralysis of characteristic distribution. The results of this inquiry were as follows:

	Cases
Gastro-intestinal symptoms followed by paralysis of	
Face	10
Lower limbs	108
Face and lower limbs	2
Upper limbs	16
Respiratory symptoms followed by paralysis of	
Face	2
Upper limbs	5
Lower limbs	50
Gastro-intestinal and respiratory symptoms followed by paralysis of	
Upper limbs	6
Lower limbs	26

Difficult micturition was followed indifferently by paralysis of the upper or lower limb.

Thus it may be concluded that there is no obvious relation between the mode of onset of the disease and the distribution of the subsequent paralysis.

Oedema of the eyelids was a presenting sign in 2 cases; both were sent in with a diagnosis of nephritis, and in neither was any evidence of kidney damage detected subsequently. In 3 cases swelling of joints was an early but transient phenomenon.

Causes of Death

Fifteen patients succumbed to the disease, death being due to respiratory paralysis in 14 and to convulsions in 1; death rate, 3.5%. Twenty-three children died from intercurrent disease, the actual causes of death being the same as those commonly found in the 0–5 years age group in Malta. It is possible that in several cases the paralysis was a contributory cause of death, but even if all fatalities are included the total death rate of 9.0% is not high in an epidemic of some magnitude; it has been suggested elsewhere (Seddon *et al.*, 1945) that this is evidence in favour of the virus being native to Malta rather than imported from another country. By contrast, the death rate among the Service cases was 19.3%, all but two of the fatalities being due to respiratory paralysis; two late deaths were attributed to cerebral anoxia.

Distribution of Paralysis

The original distribution of paresis or paralysis in all the cases is shown in Table I. It will be noticed that the lower limbs alone were affected in 219 cases (51%), and in association with paralysis of other regions in 120 cases, bringing the total of lower-limb paralyses to 339 (79.5%). The upper limbs were involved alone in 45 (10.5%), and with others in 50; cases with upper-limb paralysis thus total 95 (22.3%). The abdominal and spinal muscles were affected in 102 cases (23.9%); all except four had paralysis elsewhere. Facial paralysis occurred in 47 cases (11%); 29 of them showed no other abnormality. The spinal segmental involvement is shown in Fig. 2.

TABLE I.—*Distribution of Muscular Paresis or Paralysis (426 Cases)*

Lower limbs	57
One lower limb	162
Lower limbs; abdominal and spinal muscles	40
One lower limb; abdominal and spinal muscles	33
Upper limbs	3
One upper limb	42
One upper limb and one lower limb	16
One upper limb and both lower limbs	7
Both upper limbs and one lower limb	1
Both upper limbs and both lower limbs	1

Facial muscles	29
Generalized weakness	6

NOTE.—Facial paralysis occurred in 18 cases with paralysis elsewhere, so that the facial muscles were affected in 47 cases, or in just over 11% of cases. The sixth cranial nerve was involved in two cases in association with paralysis of the lower limbs. One of these also had a facial palsy. The incidence of respiratory paralysis is not shown; there were 15 cases among the 426.

Treatment

At first the only physiotherapists available were one masseuse and one voluntary assistant. An after-care sister from the Wingfield-Morris Hospital, Oxford, went out with one of us (H. J. S.) at the end of Feb., 1943, and remained in Malta until the end of August. The Army generously permitted the masseuse in charge of the military cases to spend nearly half of her time at the civil hospital, and thus, with the assistance of junior medical officers and V.A.D.s who were given special courses of instruction, it was possible to build up a physiotherapy service which, although admittedly inadequate, was entirely effective in preventing deformity and in providing muscle re-education for such children as were old enough to co-operate. In spite of the language difficulty it was remarkable how intelligent youngsters of 3 or 4 could be taught to carry out exercises appropriate to their individual needs.

Since most of the children were under 5 years of age plaster-of-Paris proved unsuitable for splinting the lower limbs. It was necessary to provide durable splints that would not rust. Thanks to the generosity of Air Vice-Marshal Sir Keith Park, the Air Officer Commanding, we were able to obtain sheet duralumin, from which simple but very effective splints were made. They were even lined with spongy rubber sheeting salvaged from German aircraft. For cases of paralysis of the trunk muscles Bradford frames made of gas-piping were used, the patient being supported by canvas slings and held securely by a linen jacket. Owing to the pressure of work we had at first to be content with plaster-of-Paris and light wire splints for use in paralysis of the upper limb.

The provision of a swimming-pool was not thought to be desirable. It would have been available for only a limited number of patients, it would require an abundant supply of water and fuel—there was a shortage of both—and it would have been necessary to install some form of water-disinfecting plant. Scabies and impetigo were rampant at that time. A suspension apparatus was nearly as satisfactory. Five of these appliances were made, being constructed in such a way that they could be taken to pieces and transported to a clinic by car. The woodwork was done by the carpenter at St. Luke's Hospital, and the springs and other metal fittings were supplied by Col. H. D. Tanner, of the Royal Engineers.

It was estimated that at least 150 children would require some kind of permanent apparatus. A workshop for the supply of "irons" is now in being; the materials necessary for making a start were sent out by the Crown agents, with a supply of boots, of which there was until recently an almost complete dearth.

Recovery

Table II shows the recoveries that were complete by Sept., 1944, while in Table III are details of the recoveries in the cases that still show signs of paralysis of another part of the body.

TABLE II.—*Complete Recoveries*

Distribution of Paralysis	Recovered Within (Months)									Total
	1	2	3	4	6	9	12	15	21	
Lower limbs	2	4	17	1	1	2	1			28

Total	5	9	5	9	12	35	6	3	1	85

Of the 388 survivors 152 (39.2%) made a complete recovery within 21 months (Table II); and of the 152 about two-thirds (110) recovered within the first three months—which happened to be the period when the provision of physiotherapy was very meagre. This early and unassisted recovery cannot be explained in terms of axonal regeneration; it must represent the return of function in comparatively normal anterior horn cells whose activities had been merely suspended by the disease. There is another peak in the 9–12 months period, when 30 more cases made a complete recovery; but the table suggests that in spite of adequate physiotherapy, such as became available four months after the outbreak of the epidemic, there is not much to be hoped for in the cases still paralysed after 12 months unless a still later peak is found indicating recovery due to axonal regeneration. It may well be that the 30 cases that recovered in from 9 to 12 months were those in which deliberate muscle re-education was required to complete the restoration of function. A more recent, though admittedly incomplete, review of the cases in Jan., 1945, 26 months after the outbreak of the epidemic, is not encouraging; there have been no spectacular improvements since the twelfth month.

The main peak of partial recovery in the cases which still show some paralysis (Table III) was between 9 and 12 months, which suggests that in the more severely paralysed patients physiotherapy may play an important part in bringing about such recovery as occurs.

No fewer than 102 patients suffered from abdominal or spinal paralysis, or both, usually in association with paralysis of other parts of the body. Fortunately only 21 patients have failed to recover good power in the abdominal and spinal muscles, and it is to be hoped that the incidence of structural scoliosis will be low.

The high incidence of facial paralysis—47 cases—was a remarkable feature of the epidemic; in 10 some degree of paralysis is still present and the prognosis must be regarded as bad. In the 29 cases in which there was no associated paralysis the diagnosis of poliomyelitis was based on (1) the absence of other causes, (2) the presence of the same kind of general disturbance as was observed in children suffering from paralysis of the limbs, and (3) the occurrence of the facial paralyses during the epidemic period. The recovery rate was much the same in those cases in which other parts were paralysed as it was in those in which facial involvement occurred as an isolated phenomenon.

A Plan for the Future

It was suggested to the Secretary of State for the Colonies and to the Malta Government that an orthopaedic service should be established to provide not only for the long-term care of the victims of the epidemic but for cripples of every kind. This proposal was received with enthusiasm, and in July, 1943, two more masseuses from England went out to Malta, where, under the guidance of Prof. P. P. Debono, professor of surgery in the Royal University of Malta, they established a physiotherapy department at the Bugeja (Central) Hospital in addition to taking over the work already started at St. Luke's. It is planned to train several Maltese girls at physiotherapy schools in this country, and during their time of training and for some time after they return to Malta the physiotherapy staff will be augmented by two more physiotherapists sent out from Britain.

Mr. A. J. Craig, a Maltese surgeon with experience of general and orthopaedic surgery in this country, has recently been appointed to take charge of orthopaedics in the Maltese Medical Service: he is now organizing his department, and has also been proposed for the post of Lecturer in Orthopaedics in the Royal University. The junior surgeon who was placed in charge of the cases of poliomyelitis from the time of the epidemic until Oct., 1944, is now in this country gaining further experience in general and orthopaedic surgery. In due course he will return to Malta as assistant orthopaedic surgeon. The orthopaedic workshop will form part of the permanent organization.

Conclusions

The clinical aspects of the Malta epidemic presented few unusual features. There are, however, one or two points to which attention should be directed.

One of the earliest and, apparently, most constant signs described by other observers is stiffness of the neck and back, so that the patient is unable to approximate the chin to the bent knees. This phenomenon is sometimes referred to as the "spine sign," but its diagnostic significance is evidently doubtful, since not only may it be absent in most cases of poliomyelitis, as in our series, but it may occur in any condition associated with meningeal irritation. The lack of any definite correlation between the prodromal subjective and objective phenomena on the one hand, and the distribution of the eventual paralysis on the other, is as striking as it is unfortunate; not only is the clinician deprived of a valuable pathfinder, but he may even be thrown off the scent by having al his attention directed away from the silent paralysis by the clamour of symptoms such as pain in another part, vomiting etc. This state of affairs may furnish one explanation for the "missed cases" in an epidemic.

In most disease processes the value of pain as an early localizing symptom is well recognized; it was therefore disturbing to find that the site of pain gave little or no indicatio as to the site of the subsequent paralysis. Muscle tendernes was also inconspicuous. The same was true of the viscera symptoms: there was no more likelihood of a patient developing paralysis of the lower limbs after a gastro-intestinal upse than after a prodromal respiratory disturbance. The occurrenc of paralysis of the lower limbs in four out of every five of ou cases is in keeping with the findings reported by most othe observers.

A curious feature of the epidemic was the high incidenc of facial paralysis. It was invariably unilateral, and in th majority of cases disappeared during the first three month Persistence of the paralysis after that period was accompanie by reaction of degeneration in the affected muscles, and th prospect of recovery must be extremely poor. This was als our experience with regard to paralysis of any part of the body. The largest number of recoveries took place during the first three months after onset—at a time (as it happened) when little physical treatment was available. A second though much smaller peak in the recovery rate, which occurred during the 9–12 months period, may have been due in part to the influence of treatment. Although the part played by physiotherapy seems to be small, in that no known treatment can bring about regeneration of grossly damaged anterior horn cells, the prevention of contractures and the maintenance of joint mobility are of great value. When recovery is slow and imperfect the importance of muscle training is especially noteworthy. It is therefore only in the early and complete recoveries that physical treatment seems superfluous.

The care of the victims of this epidemic was and still is the work of a team. In addition to those whose names appear in the text we express our thanks to Prof. A. V. Bernard; to the resident medical staff of St. Luke's Hospital, especially to Dr. O. Azzopardi and Dr. V. Zammit-Tabona; to the physiotherapists, Mrs. K. J. Bell, Miss E. J. Charter, Miss P. Empson, Mrs. M. T. Ensoll, and Miss M. B. Quinton; and to the Reverend Mother Superior and her devoted staff of nurses.

ACUTE ANTERIOR POLIOMYELITIS AMONG SERVICE PERSONNEL IN MALTA

AN ACCOUNT OF AN EPIDEMIC

BY

H. G. G. BERNSTEIN, M.B.E., M.B., Ch.B.
Major, R.A.M.C.; Medical Specialist

J. M. P. CLARK, M.B., Ch.B., F.R.C.S.
Major, R.A.M.C.; Orthopaedic Specialist

AND

R. E. TUNBRIDGE, O.B.E., M.D., M.Sc.
Lieut.-Col., R.A.M.C.; Officer in Charge, Medical Division

An account is given of the clinical pathological, and therapeutic findings in a series of 57 cases of acute anterior poliomyelitis occurring among Service personnel during the Malta epidemic of the winter of 1942–3. The epidemiological findings of the outbreak have been fully discussed elsewhere by Seddon, Agius, Bernstein, and Tunbridge (1945). Only 4 out of a total of over 400 cases were recorded among the adult Maltese population and none at all among the Maltese troops. The apparent immunity of the Maltese troops is the more striking because they were often working side by side with United Kingdom troops.

Of the 57 cases 2 were from the Royal Navy, 27 from the Army, and 28 from the Royal Air Force. The incidence was proportionately higher among the R.A.F. than among the Army personnel, being 4 to 1. The duration of service in Malta bore no relation to the disease. The average duration among affected personnel was over 12 months (Table I). The four cases with less than one month's service in the island arrived after the onset of the epidemic. The average duration of the disease before admission to hospital was 3.6 days, with a range from 12 hours to 15 days.

TABLE I

Duration of stay in Malta:		Period of service:	
1 month and under	4	Minimum	2 weeks
1 to 6 months	7	Maximum	5⅔ years
7 „ 12 „	4	Average	Over 12 months
13 „ 24 „	31		
Over 2 years	11		

The Preparalytic Stage

In only two instances was information regarding the preparalytic stage not available. In two further cases no paresis developed, and in five additional cases the exact duration was difficult to assess as there was in each instance a history of illness followed by a period of normality lasting 3 to 12 days before the return of symptoms and the onset of paralysis. The average duration of the preparalytic stage in the remaining 48 cases was 3.4 days (Table II).

The proportion of non-paralytic cases was unusually low, and undoubtedly some cases were missed. On the other hand, the medical officers and all the troops were aware of the prevalence of anterior poliomyelitis, with the result that almost all those complaining of headache and fever during the peak period of the epidemic had a routine examination of the cerebrospinal fluid on admission to hospital. By this procedure the diagnosis was established in the two recorded non-paralytic cases.

TABLE II.—*Duration of Preparalytic Period*

12 cases	24 hours or less	6 cases	4 days
6 „	2 days	7 „	5–7 days
11 „	3 „	6 „	8 days or more

(Average 3·4 days)
5 cases with uncertain preparalytic period (2 or 10, 5 or 14, 3 or 15, 1 or 4, 3 or 10 days);
2 cases, no paresis; 2 cases, data not available

Symptoms.—In 36 cases the onset was sudden and dramatic, the patient presenting some of the symptoms and signs of meningeal irritation. Headache was the most prominent initial symptom, and was recorded in 45 cases (Table III). No new symptoms were observed, nor was there a constant clinical picture applicable to the majority of cases.

TABLE III.—*Preparalytic Symptoms in 53 Cases*

Headache	45	Anorexia	8
Muscle weakness	26	Vomiting	6
Pain in back	21	Lassitude	6
„ neck	14	Urinary symptoms	5
„ limbs	13	Abdominal pain	4
Malaise	14	Dysphagia	3
Sore throat and coryza	13	Weakness of eyes	2
Shivering attack	11	Miscellaneous	5

Signs.—Pyrexia was noted in 43 cases on admission to hospital, and ranged from 98.8 to 104° F. The fever lasted from 48 hours up to eight days, save in six cases in which the development of secondary infection, respiratory or urinary, prevented an accurate assessment of the duration of pyrexia attributable to the primary disease. Neck rigidity was observed in 20 cases, neck stiffness in 17, Kernig's sign and the spine sign in 12.

The Paralytic Stage

Twenty-six patients complained of weakness of a limb or other part of the body before admission. Muscle tenderness was noted in 30 cases, but in only six did it present with any degree of severity longer than 10 days after the onset of the paralysis. The degree of muscle tenderness bore no relation to the severity of the muscle paresis. In the present series the degree of paralysis was by no means maximal within 24 hours of onset (Table IV).

TABLE IV.—*Cases with Delayed Spread of Paresis*

	Cases		Cases
2 days	2	6 days	1
3 „	3	9 „	1
4 „	3	10 „	1
5 „	2		

(In 8 cases delayed 4 days and over)

The spread of the paralysis was descending in 10 and ascending in 3 cases. In 15 cases the development of the paralysis was not continuous, but was of the "jumping"-variety, with an interval of at least 12 hours between the jumps. Included in the jumping cases were nine of the descending and three of the ascending type of spread. Accurate assessment of the extent and the degree of paralysis in the initial stages was often a matter of considerable difficulty. In our experience neither the degree of loss of power nor the degree of alteration of the reflexes was of itself an adequate guide to the severity. Some cases with absence of reflexes in the early stages made a dramatic recovery of power, and vice versa. Further, despite repeated and careful examination, muscles apparently unaffected initially, or even after 10 days, showed definite weakness three to five weeks later. The latter feature is of considerable clinical significance and necessitated keeping the patients in bed for at least four, preferably six, weeks. However trivial the initial paralysis may seem, it is only by keeping the patient in bed for such a period that the extent of the paralysis can be fully assessed and the development of deformity minimized.

Case 14.—Sgt. H., aged 21. Admitted to hospital with a two-days history of headache and pain in the neck. The next day he developed weakness of the muscles of the right shoulder, mainly of the right deltoid. Cerebrospinal fluid: 88 cells per c.mm. (polymorphonuclears); protein, 50 mg. per 100 c.cm. No further muscle weakness was recorded during the first three weeks of the illness. Allowed up after one month, when he complained of weakness of the legs. Examination showed weakness of the abdominal, hip flexor, and quadriceps muscles of both legs.

The final distribution of the paralysis for all patients is given in Table V.

TABLE V.—*Distribution of Paralysis*

Cranial nerves:		
Alone	3	14 (24·5%)
With others	11	
Respiratory system (Fatal cases, 11)	16	(28%)
Arms:		
Alone	7	35 (61%)
With others	28	
Legs:		
Alone	3	38 (66·7%)
With others	35	
Trunk:		
Alone	2	28 (49%)
With others	26	
Sphincters:		
Bladder	10	12 (21%)
Bladder and rectum	2	

Respiratory paralysis was observed in 16 cases. The initial symptom was an inability to take a deep breath, and was always complained of by the patient before the detection of any weakness of the respiratory muscles on physical examination. The earliest sign was a weakness of the cough reflex. In at least four cases death was due to central rather than peripheral failure. Patient No. 6 died six and a half months after the onset of the disease, and during the last 12 hours of life had a series of convulsions, each of some minutes' duration, and completely unaffected by the continuous use of the Drinker respirator; necropsy showed no evidence of cerebral abscess or embolus. Analysis of the cases revealed that the later the development of respiratory symptoms after the onset of the disease the greater the prospect of recovery.

Cranial Nerves.—An unusual feature was the presence of nystagmus in 10 cases. In the non-fatal cases the nystagmus rapidly disappeared and was not present after six weeks. In two of the early cases, although nystagmus was observed and recorded, it was not then considered to be due to the virus infection—e.g., Case 26, with diagnostic C.S.F. findings, had nystagmus and a mild degree of weakness of the dorsiflexors of the right ankle and slight diminution of the right ankle-jerk as the only abnormal physical signs. The following cranial nerves were involved: 7th (3 cases), 4th and 6th (2 cases), 12th (1 case). Three patients complained of dysphagia and one case of diplopia. In the civilian cases there was also a high incidence of cranial nerve lesions—11% had facial palsy.

Sphincters.—Retention of urine occurred in 12 cases. In eight the retention was of short duration, lasting only from 36 hours to six days. Suprapubic cystostomy was performed in one of the remaining cases; catheterization was necessary in a further two, and in the remaining case hesitancy still persisted after three months. Two cases had incontinence of faeces in addition to retention of urine.

Recovery.—The rate and degree of recovery varied considerably. Owing to the exigencies of the Service it was impossible to record the final disposal of every case, but in all save seven it was possible to assess the degree of paralysis after three months. Table VI classifies the cases according to the severity of the paralysis.

TABLE VI.—*Severity of Cases: Review Three Months after Onset*

	Non-paralytic	Slight	Moderate	Severe	Fatal	Total
Royal Navy	—	2	—	—	—	2
Army	2	6	2	11*	6	27
Royal Air Force	—	6	8	9	5	28
Total	2	14	10	20	11	57

* Two severe cases are likely to prove fatal within one year.
Non-paralytic = Positive symptoms and C.S.F. findings; no paralysis.
Slight = Mild paralysis; fit for full duty within three months.
Moderate = Definite paralysis, but ultimately should have no serious disability.
Severe = Cases likely to have permanent disability.

Diagnosis

During the epidemic cases of infective hepatitis, undulant fever, enteric fever, fibrositis, infective neuritis, sciatica, pleurisy, coryza, disseminated sclerosis, diphtheritic polyneuritis, cerebral abscess, and hysteria were sent to hospital labelled anterior poliomyelitis. By contrast one or two cases were missed, and were referred to hospital only when the paralysis was fully established. The cerebrospinal fluid findings, together with the clinical history and the distribution of the paralysis, were adequate for establishing the diagnosis. During an epidemic of acute anterior poliomyelitis in a subtropical climate great difficulty may be experienced initially in differentiating between sandfly fever, benign lymphocytic meningitis, and a non-paralytic case. The high percentage of lymphocytes on initial examination of the cerebrospinal fluid in the present series of cases suggests that it is necessary to exercise caution in making a differential diagnosis in the above conditions purely from the cytological examination of the cerebrospinal fluid.

Once paralysis is established difficulty may arise in a mild sporadic case in differentiating between muscular dystrophies, localized neuritis of shoulder-girdle distribution (Spillane, 1943), and acute anterior poliomyelitis.

Three cases were of special interest in that the diagnosis was a matter of considerable difficulty.

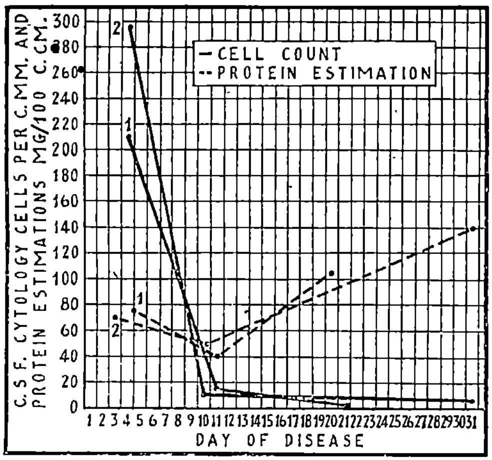
Case 15.—Pte. S., aged 26. Admitted to hospital for dental treatment while convalescent from enteric fever. Five days after admission he developed bronchitis, and five days later weakness of the right serratus anterior was observed. The diagnosis of anterior poliomyelitis was discussed, but was considered unlikely by the physician in charge and by the surgical specialist. Lumbar puncture was not performed. A plaster abduction splint was applied, and while in the splint the patient complained of weakness of the right elbow and wrist. Removal of the plaster after three weeks revealed weakness of both serratus anterior muscles, the spinati, right triceps, and extensor muscles of right wrist. Prof. H. J. Seddon examined the case and agreed finally with the diagnosis of anterior poliomyelitis.

Case 55.—P/O. T., aged 23. Contracted syphilis seven months before admission. He was having antisyphilitic treatment, and had received nine injections of arsenic. He piloted his plane two days before admission, and the following evening complained of weakness of the right leg; a diagnosis of transverse myelitis, ? syphilitic, was considered. The next day, on admission to hospital, flaccid paralysis of the right leg and weakness of the left leg, with no sensory changes, were observed, and the cerebrospinal fluid showed 170 cells (lymphocytes and monocytes) per c.mm. and 200 mg. protein per 100 c.cm.; second day in hospital, paralysis of both legs and weakness of lower abdominal muscles; third day, paralysis of the left half of the diaphragm (blood Kahn ++); fourth day, all abdominal muscles and left half of chest paralysed, and he was placed in a Drinker apparatus; fifth day, paralysis of both sides of diaphragm. Death occurred on the seventh day. Necropsy revealed oedema of the brain with flattening of the gyri, no naked-eye evidence of haemorrhages into the spinal cord, congestion of the lungs, right-sided heart failure, and slight enlargement of the spleen. The micro-anatomy of the nervous tissues is not yet available. There was no microscopical evidence of any syphilitic changes.

Pte. C., aged 27.—On admission, after a history of one day's pain in the limbs and in the neck, this case presented the physical signs of a transverse myelitis, the upper level of the sensory loss being D 9. Wasting of the whole of the erector spinae muscles and of the muscles of the left arm, with a distribution typical of anterior poliomyelitis, developed after admission. The blood Kahn reaction was repeatedly negative and there was no history or clinical or pathological evidence of a syphilitic infection. Brig. D. MacAlpine at first thought the case might be one of anterior poliomyelitis, but in view of the progress of the patient it was later diagnosed as transverse myelitis, and is not included in the present series.

Pathology

Cerebrospinal Fluid.—Lumbar puncture was performed within 24 hours of admission, and in 24 cases was repeated at least once after 7 to 10 days. In 21 cases lumbar puncture was performed on at least three occasions—on admission, at 7 to 10 days, and again 14 to 21 days after the onset of the disease. No definite relation existed between the cell count, the protein content, and the severity of the disease. The cell count was high in the majority of cases. The cells were mainly lymphocytes and monocytes, but in a few instances the polymorphonuclears predominated. In the 11 fatal cases the count upon admission ranged from 100 to 900 cells per c.mm. On the other hand, two severe cases had initially a count of only 40 cells per c.mm. In the series only three cases had a normal cell count upon admission, and in one of these the protein content was raised. In the two non-paralytic cases the cell counts were 112 and 200 respectively—lymphocytes and monocytes predominating. Repeated examination of the cerebrospinal fluid confirmed the findings of previous workers that the cell-count steadily falls, reaching normal limits in 10 to 21 days, whereas the protein content remains raised or continues to rise for 2 to 4 weeks. In a few instances the protein content fell to within normal values after 10 to 13 days, then rose again. This suggests that the finding of a normal cerebrospinal fluid between the 10th and 14th days in a suspected case of acute anterior poliomyelitis does not necessarily exclude the diagnosis (see Graph).



Graph illustrating the fall of the cerebrospinal fluid protein content and the cell count to within approximately normal limits between the 10th and 14th days of the disease in certain cases.

Leucocyte Count.—Examination of the white-cell count was not made as a routine, and the data available were too limited to permit of any conclusions.

Post-mortem Examination

Necropsies were made in all fatal cases—11 adults and 1 child; the latter is excluded from this report. In nine cases death occurred during the acute stage of the illness, and in the remaining two cases after four and a half and six and a half months respectively from the onset of the disease. The spinal cords and brains from four cases were preserved intact and sent to the Central Laboratory, G.H.Q., Cairo, for micro-anatomical and virus examination. Faeces and urine from one fatal case were also sent. In the nine cases in which death occurred during the acute stage the brain was described as oedematous or congested, and the gyri as flattened. Medullary haemorrhages were reported in six cases, pontine and mid-brain haemorrhages in three.

Cardiovascular system: Right-sided dilatation of the heart and congestion were reported in eight cases. Lungs: Congestion was reported in seven cases, collapse in three, bronchopneumonia in three, and pneumonic consolidation with acute abscess formation in one case. The spleen was enlarged and friable in five cases. The liver and kidneys were stated to be congested in five cases. Tardieu spots were reported in four. The principal finding in the two patients dying after the acute stage was right-sided heart failure. In one the lungs were healthy, and in the other there were mild bronchopneumonic changes. The brains showed no macroscopic evidence of congestion, oedema, or haemorrhage.

Treatment

Ward Management.—All doubtful cases were admitted to one ward, where full precautions were taken. The staff wore masks and gowns; the patients had individual crockery, and all faeces and urine were disinfected. Once the diagnosis was established the cases were transferred to another ward. A portion of the latter was set aside for the treatment of cases with respiratory paralysis. At the end of 10 days all cases not requiring the use of the Drinker apparatus were transferred to a convalescent ward, where no further precautions were taken concerning the possible spread of the disease.

Serum Therapy.—Serum was not used in the early cases, the work of the Rockefeller Institute and the Australian Commissions having led us to believe that its use was of little value. Serum, however, was forwarded from the Middle East, and 13 cases received convalescent serum in doses varying from 20 to 150 c.cm. The dosage used was 10 c.cm. intravenously and 40 c.cm. intramuscularly daily for three days. No serum reactions were observed.

Sulphadiazine.—In addition to the serum 10 cases received sulphadiazine. The dosage advised by Brig. MacAlpine was 3 g. twice daily for four days and then once daily for two days. The 3-g. dose was dissolved in 10 c.cm. of distilled water and injected slowly over a period of three minutes. Of the 10 cases only three had the full course. Four cases developed frank haematuria after the administration of 9 to 12 g.; one case had red cells in the urine after 18 g.; one case developed severe vomiting after 12 g.; the remaining patient had to be placed in the iron lung, and died before the completion of the course. Of the 10 patients receiving both serum and sulphadiazine two died. The number of cases treated was too small to be of statistical significance, and owing to the development of complications only three had a complete course. No dramatic improvement seemed to follow the use of this therapy, but, in view of the long preparalytic period in some cases, we feel that it is worthy of a more extended trial.

Respiratory Paralysis.—The serious therapeutic problem during the early stages was the treatment of respiratory paralysis. In these stages of the epidemic sufficient mechanical respirators were not available and respiration was maintained manually. None of the recognized methods of artificial respiration (Schäfer, Silvester) was tolerated by the patients. The only effective method was rapid pressure and release (30+ per minute), applied centrally with the palm of the hand on either side of the lower end of the sternum. One of us (R. E. T.). on observing this, reprimanded the orderly for using an unsound method, as he considered that any benefit derived from such a procedure must be psychological rather than physiological. Further experience suggested that this supposition was untrue, for the unorthodox method did relieve cyanosis, which the orthodox methods failed to do because they distressed the patient. We consider that the reason for the anomaly was the painful character of all movement of the chest on account of the tenderness of the affected muscles.

Through the generosity of the civil Government three iron lungs of the Nuffield pattern were lent to the Army. Lieut.-Col. Tanner, R.E., constructed three respirators of the Drinker type, incorporating several minor modifications which made for greater efficiency. Several Bragg–Paul respirators were sent to the island upon the instructions of the War Office. As a result of the experience gained in the epidemic we found that the Drinker type of artificial respirator did relieve cyanosis—even when all other methods had failed—induced physiological respiration, and gave the patient comfort and confidence. whereas little benefit was derived from the use of the Bragg–Paul type, either in the acute stages or in the treatment of cases still requiring the use of artificial respirators after three months. Oxygen was administered in the cyanotic cases, the B.L.B. apparatus being used.

Sepsis.—Respiratory and urinary sepsis were treated with full courses of sulphapyridine and sulphathiazole. For the lung infections postural drainage was attempted, but in the acute stages of the disease proved too distressing to the patient. The local treatment for infection of the bladder consisted of alternate washouts with oxycyanide of mercury (1 in 10,000) and boric acid solutions.

Muscular Paralysis.—The problem from an orthopaedic standpoint consisted in retaining the muscles in a neutral position during the acute stage, in providing varying forms of splintage to prevent stretching of the paralysed muscles and contracture of their antagonists, and in giving suitable remedial treatment in the convalescent stage pending evacuation of the cases from the island.

Acute Stage.—The neutral position adopted was the supine, with a low pillow just raising the shoulders to avoid stretching the abdominal muscles (as in many cases these particular muscles were affected), but not high enough to stretch the paravertebral groups. The head was similarly supported. The upper limbs were placed in the hips-firm position, the fingers resting lightly on the abdomen just above the iliac crests, with a reasonable degree of abduction of the shoulders maintained by means of sandbags. The legs were placed together and extended, with the feet supported at a right-angle with a foot-board or with short back splints. Behind the knees a low pillow was placed, giving about 10 degrees of flexion—a position in which there is very little risk of stretching the quadriceps and which avoids the graver danger of the development of genu recurvatum. The legs and feet were further protected with a bed cradle. This position was assumed by all patients except those whose respiratory paralysis necessitated the use of an iron lung, in which provision for the best posture for the arms is absent. An iron lung of the Drinker pattern constructed locally was furnished with an adjustable foot-rack, and a second one was projected in which abduction of the arms could have been accomplished, but the epidemic subsided before the machine was completed. It is noteworthy that all patients who had been treated in the iron lung either developed contractures in the pectoral groups of muscles or experienced discomfort in them during the passive abduction. The neutral position was maintained until the pain and tenderness had gone and the convalescent stage was reached.

Treatment in the Convalescent Stage

All the muscles of each patient were investigated methodically, and as nearly as possible in the clinical examination the power of each individual muscle was assessed and classified according to the M.R.C. nomenclature at 7-day to 10-day intervals. The majority of cases showed paralysed muscles or muscle groups, occurring in all limbs and the trunk indiscriminately. All the cases in which the trunk and lower limbs were affected were maintained in the neutral position, and, where possible, were permitted use of the arm—either unsupported, if the muscles had escaped paralysis, or suitably splinted according to the muscle groups involved.

A notable feature of many cases was paralysis of the abdominal muscles, including the lateral abdominals, the asymmetrical affection of which is so potent in producing a gross scoliosis unless preventive measures are undertaken. Two such cases, in which there was no respiratory paralysis, were immobilized in plaster jackets preparatory to evacuation from the island. Plaster beds would have been preferable, as physiotherapy could have been continued, but they are difficult to adapt for air travel. No patients with lower-limb weakness were allowed to walk save where such weakness was confined to the anterior tibial group, and for these a short walking calliper with drop-foot springs was supplied.

In some patients the paralysis was confined to muscles of the shoulder girdle, and these were given abduction splints. One patient whose main weakness showed in the rhomboids derived considerable benefit from wearing a figure-of-8 bandage, applied as in the treatment of a fractured clavicle. Arm weakness in the patient kept in the supine position on account of trunk and lower-limb paralysis was countered by maintaining abduction at the shoulder with light metal trough splints or plaster splints slung to a transverse bar at the head of the bed. Wrists were supported by short cock-up splints combined, in cases showing paralysis of the intrinsic muscles of the hand, with a knuckle-duster attachment; where the long finger extensors were affected the splint was continued to finger-length. If the thumb was also affected the digit was held into the palm to avoid stretching the muscles of opposition. In one patient the intrinsic muscles of the foot were involved and the toes began to assume a clawed position. For this deformity a pair of wooden sandals were supplied with four slits cut out at the front end, and the proximal phalanges of the toes were bandaged to the intervening prongs.

No limb was completely immobilized, and during the convalescent period light massage and appropriate active exercises were given daily. No active movements were carried out until muscle tenderness had completely subsided, and only such passive movements were used as were unavoidable during nursing. Once active movements had been started particular care was taken to stop them short of fatigue.

All the patients, with the exception of those who required treatment in the iron lung, carried out gymnastic exercises for all muscle groups in warmed water in a specially constructed seven-feet-long pool (funnel-shaped to provide the maximum of room for exercise in the minimum of water in order to economize in fuel for heating and to reduce the rate of heat loss) furnished with rigid head-rests and a supporting pelvic sling on a crane. These water exercises were performed three times weekly, and were very popular with the patients because they seemed to be effortless, a rough idea of progress could be measured by the patients themselves, and the much greater excursion of voluntary movement while in the water was psychologically stimulating.

For those patients who had respiratory paralysis—and in all of them the paralysis of the remainder of the trunk and the limbs was widespread—a suspension frame for the carrying out of active exercises was constructed to imitate the effect of a swimming-pool so far as was possible. The upper limbs were supported on a light metal trough, with troughs for the upper arm and forearm, leaving the shoulder and elbow free, while the wrist was supported by chaining wooden hand-grips to the forearm troughs. These troughs were suspended from the frame by selected cords, attached to the frame by springs made of coiled piano wire. Resistance to the movement was minimal, and the springs afforded considerable resilience to such movements as could be executed. An extension of the frame enabled the lower limbs to be treated similarly, and the active pressing down of the lower limb against the supporting springs proved to be particularly good for exercising the gluteal muscles. In one case a further addition to the frame was a hand-pulley device for exercising the feet by pulling down the hinged foot-pieces of the lower-leg troughs against the counter-springs.

Discussion

The most striking feature of the epidemic was the almost complete absence of cases among the adult Maltese population. This fact, coupled with the high incidence among Maltese infants, would be compatible with the view that the strain of virus responsible for the epidemic was one for which the adult Maltese had some degree of immunity, but not the adults from the United Kingdom. The above facts are also of interest in the elucidation of the origin of the epidemic. Before the outbreak Malta had been besieged, and contacts with the outside world were limited to the movements of a small number of Service personnel. As a result the question of the epidemic having been introduced by the Service had to be considered. Prof. Seddon, after a careful analysis of all the cases, concluded that there was no evidence to support the view that the epidemic was introduced by Service personnel.

The case incidence was high—approximately 150 per 100,000—but the mortality rate was not abnormally high either for the epidemic as a whole or for the adult cases. The unusual clinical features were the high incidence of cranial nerve lesions in both the civilian and the Service cases and the presence of nystagmus in 10 of the latter (17%). Further, in view of the recent controversy concerning the early treatment of acute anterior poliomyelitis, the frequent finding of selective muscle weakness as late as the fourth week after onset suggests that the age of the subject should be taken into consideration before generalizations concerning therapy are made. As a result of the experience gained in the epidemic described, we consider that for an adult case a minimum period of six weeks' absolute rest is advisable.

Treatment of the patient with respiratory paralysis raised many problems. Of the 16 cases with respiratory paralysis 13 were treated in a mechanical respirator. Of the 13 so treated 10 died, and two further cases have such a serious degree of paralysis that they are likely to succumb to a secondary respiratory infection within two years. The distressing appearance of such patients often leads the physician to make frantic demands for a mechanical respirator on misguided humanitarian grounds. In a considerable proportion of cases, more particularly those in which the paralysis begins within five days of the onset of the disease, the respiratory failure is central in origin and no form of artificial respiration is of avail. Morphine, used judiciously, would seem to be the treatment of choice for such cases.

The mechanical respirator, however, has a value in the treatment of cases in which the paralysis is peripheral. In our experience the later the onset of the respiratory paralysis the more likely was it to be peripheral in distribution. In the treatment of respiratory paralysis two varieties of mechanical respirator were used—the Drinker cabinet respirator and the

Bragg–Paul pulsator. In our series the former proved to be the only effective method of artificial respiration. We attribute the failure of the Bragg–Paul pulsator to: (*a*) the limited area of application, which prevents the machine from completely dominating the respiratory action; (*b*) the tenderness of the affected muscles, which induces spasm; (*c*) inability of the machine, when it cannot dominate respiration, to adapt itself to the constantly varying respiratory rhythm; (*d*) the faulty principle of the pulsator, in that inspiration is not purely passive; (*e*) the noise made by the bellows, which is such that the patient tends to expire when he should inspire. Although the Drinker respirator was of value, the constant use of the apparatus required the continuous attention of skilled mechanics and an unfailing supply of electricity. Further, since cases with respiratory paralysis often had widespread muscle involvement the long-continued use of the ordinary type of cabinet respirator prohibited the treatment necessary for prevention of contractures of the upper limbs.

In view of the above facts and the difficulty of transporting artificial respirators it would seem advisable to centralize treatment. It is our considered opinion that for a small outbreak it would be preferable to transfer patients in the initial stages, if necessary by air, to a centre adequately supplied with respirators and full physiotherapeutic facilities rather than to transport respirators.

Summary

The clinical and pathological findings and the early treatment of a series of 57 adult cases of anterior poliomyelitis occurring among Service personnel during the Malta epidemic 1942–3 are described.

There were 11 deaths—a mortality rate of approximately 19%.

In 2 cases no paralysis was noted. In 26 (45%) cases there was no serious final disability.

In 14 (24%) cases the cranial nerves were involved; in 16 cases there was respiratory paralysis; and all the deaths resulted from respiratory paralysis, despite the use of a mechanical respirator of the Drinker cabinet pattern; in 12 (21%) cases there was disturbance of the sphincters.

Convalescent serum and sulphadiazine were used in a small number of cases without any apparent benefit.

The onset of the paralysis was often delayed, and in a few instances was not apparent until the fifth week.

We wish to thank colleagues for their help: Capt. J. C. Lees, R.A.M.C.; Major I. MacPherson, R.A.M.C.; Major A. Charles, R.A.M.C.; Major E. Geal, R.A.M.C.; and Capt. W. S. A. Oakes, R.A.M.C. Also Miss A. M. MacHardy, Q.A.I.M.N.S.(R.), Miss K. Taylor, Q.A.I.M.N.S.(R.), and Sgt. H. E. Fisher, R.A.M.C., for their nursing skill; Mrs. Bell, Massage Corps, for assistance with the massage; Prof. H. J. Seddon and Brig. MacAlpine for their interest and stimulating advice; Lieut.-Col. H. D. Tanner, R.E., for his technical skill and assistance in constructing, under difficult circumstances, the respirator, swimming-pool, and splints; and Brig. W. K. Morrison, D.S.O., D.D.M.S., Malta, for permission to publish this paper.

THE ERYTHROCYTE SEDIMENTATION RATE IN INFECTIVE HEPATITIS*

BY

J. A. R. MILES, M.B., B.Ch.

In recent years a number of references to the erythrocyte sedimentation rate in infective hepatitis have been published. Ziegler (1941) found that a rise in the E.S.R. often occurred in children in the second or third week after the onset of icterus. Penman (1943), reporting hepatitis in tuberculosis patients in a sanatorium, stated that in about one-half of a series of patients the E.S.R. was markedly slowed when the jaundice was at its worst, but had returned to approximately the pre-jaundice level by the next monthly examination. Any change for the better or worse could not be attributed to the tuberculous process. More recently Wood (1945) gave figures for a small series of cases in the Mediterranean area showing readings below 10 mm. (Wintrobe) in 85% in the first 10 days of the disease and later rising.

In the present investigation the E.S.R. has in 80 cases of infective hepatitis been followed throughout their stay in hospital, and observations on a few other cases seen in the pre-icteric phase are reported. Wintrobe tubes were used and the mixed ammonium–potassium oxalate anticoagulant of Wintrobe and Landsberg (1935). Corrections were made for variations in the volume of packed erythrocytes, using the chart published by Whitby and Hynes (1938).

In 40 of the 80 cases the E.S.R. was raised above 10 mm. at some stage of the disease, and it was noticed that in these cases the E.S.R. was low in the acute stage except in a few very mild cases, and then became raised as the patient recovered. Figs. 1 and 2 are graphs in which the bilirubin level and E.S.R. are shown throughout the course of the disease in two severe cases. No relation between the maximum height of the E.S.R. and the clinical severity of the case could be found.

Two Service cases were seen in the pre-icteric phase, and both these had raised sedimentation rates. One of them developed jaundice in hospital, and as his jaundice increased his E.S.R. fell, to rise again to a maximum of 29 mm. at the time when the serum bilirubin was about 1.5 mg. per 100 c.cm. (Fig. 3). Six further pre-icteric cases had sedimentation rates measured in the pre-icteric phase. In four of these the rate was raised. Two of this last group were tested again after they became jaundiced: one, who had become moderately jaundiced, showed a normal E.S.R. in the icteric phase; the other, with only conjunctival icterus, did not show any fall to a normal E.S.R. Of the six cases with an increased rate in the pre-icteric phase, two were raised above 30 mm. in one hour. In five cases the E.S.R. was raised at the time of admission. In one of these the highest recorded bilirubin was 2.3 mg. per 100 c.cm. at the time of admission, and his sedimentation rate of 35 mm. on the same day was the highest recorded.

Particulars of the case of Bdr. C., who was admitted in the pre-icteric phase, are shown in Fig. 3. His bilirubin never rose above 4.8 mg. per 100 c.cm., and his lowest recorded sedimentation rate was 12 mm. in one hour. The other three cases were also clinically mild, having 3, 5.75, and 8.5 mg. per 100 c.cm. as their highest bilirubin, and their E.S.R. continued to rise while the bilirubin was falling.

The mean sedimentation rate of all readings at various bilirubin levels has been estimated in those cases which had a raised E.S.R. at some stage in the disease, and the results are shown in Table I. It can be seen that in this series there is a rise in the E.S.R. as the serum bilirubin falls. The coefficient of correlation is –0.57. The highest recorded E.S.R. in the cases showing some rise, after correction for differences in haematocrit, varied between 11 and 42 mm. in one hour.

TABLE I

Serum Bilirubin in mg./100 c.cm.	Number of Readings	Mean E.S.R. (mm. in 1 hour)
10+	20	5·30
8·1–10	18	8·39
6·1–8	12	8·00
4·1–6	18	10·56
2·1–4	29	14·31
0–2	34	18·94

The existence of a raised sedimentation rate at least as often in the pre-icteric as in the post-icteric phase in this series, and the very marked negative correlation between the serum bilirubin and the E.S.R., suggest strongly that the normal E.S.R. in the icteric phase is due to some factor inhibiting sedimentation. On the other hand, the sedimentation rate is not so closely bound to the bilirubin figure as to suggest that the normal figure for the E.S.R. in the icteric phase is entirely due to the raised bilirubin (see, for instance, Fig. 3). The following experiments were therefore carried out to discover whether the most obvious abnormalities in infective hepatitis—increased amounts of bile salts and bilirubin in the plasma—were capable of inhibiting the raised E.S.R. in patients with tuberculosis, rheumatic fever, and infective arthritis, or those convalescent from infective hepatitis.

Methods

Oxalated blood was taken, using a minimal amount of Wintrobe's ammonium–potassium oxalate mixture, and cells and plasma were separated as soon as possible. The cells were washed in normal saline three times in the initial experiments, and in all later experiments six times. A crude bile-salt preparation was dissolved in part of the plasma, and varying final concentrations of bile salts were obtained by mixing untreated plasma with the bile-salt solution in plasma in varying proportions. Pure bilirubin was dissolved in N/20 Na_2CO_3, in 0.85% NaCl at 80° C., and brought back to *p*H 7.5 by the addition of N/1 H_2SO_4, so that the final concentration of bilirubin was 60 mg. per 100 c.cm. Gordon and Wardley (1943) had brought evidence to show that the E.S.R. can be related to the proportions of the various types of protein rather than their absolute amounts, and it was hoped that the electrolyte mixture would have little effect on the E.S.R. When it was present in a dilution of 1 : 6 in plasma the effects were slight, but at 1 : 3 it had a marked inhibitory effect. Washed cells and treated or untreated plasma were mixed in equal volumes, and Wintrobe sedimentation tubes were set up after varying periods. Normally the fall in one hour was read, and the tubes were then spun to find the volume of packed cells and the results corrected for any variations.

---

* A report to the Medical Research Council.

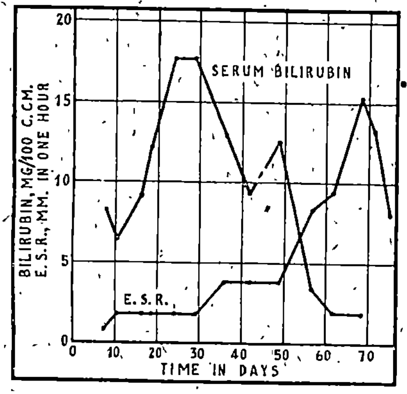

Fig. 1.—Pte. R.

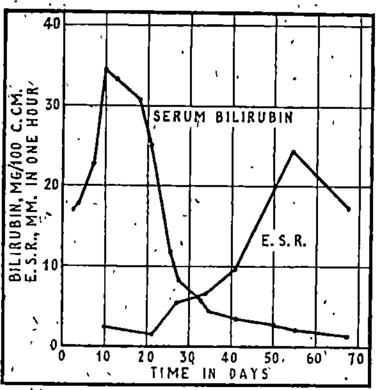

Fig. 2.—Tpr. C.

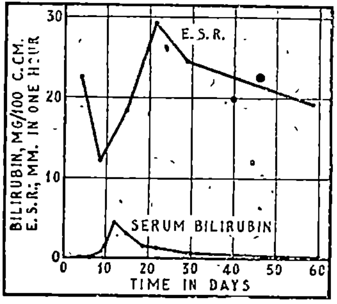

Fig. 3.—Bdr. C.

Experimental

In preliminary experiments it was found that no inhibition of sedimentation occurred immediately after the addition of crude bile salts up to 20 mg. per 100 c.cm., but that if the mixture were left at +2° C. for 18 hours quantities down to 13.4 mg. per 100 c.cm. gave definite inhibition.

In most non-malignant conditions the E.S.R. falls steadily when the blood is stored, and evidence has been put forward by Koster (1937) to show that this is due to diffusion of potassium ions from the erythrocytes into the plasma. Usually when the blood was stored overnight the E.S.R. had fallen too low for any useful observations to be made. Therefore in most experiments the E.S.R. was estimated after blood had been left at 2° C. for 1 to 4 hours. A typical result is shown in Table II.

Table II

	Corrected E.S.R. (mm. in 1 hour)	
	After Storing 1 Hour	After Storing 4 Hours
	mm.	mm.
Untreated plasma	30	20
+ 12·5 mg. bile salt ..	29·5	10
+ 25 ,, ,, ,, ..	20	8
+ 50 ,, ,, ,, ..	1	1

It will be seen that when added bile salts were 25 mg. per 100 c.cm. there was some definite inhibition after one hour. When the mixture was stored four hours the E.S.R. in all tubes was lower, but there was definite inhibition at 12.5 mg. per 100 c.cm., as against controls. In cases in which 6.25 mg. per 100 c.cm. of bile salt was added there was no inhibition. The percentage inhibition was related to the amount of bile salts added and the time given them to act, and was approximately the same for all types of case. It was not affected by the initial height of the E.S.R.

Because of inhibition due to the solvent alone it was not found possible to try the effects of more than 10 mg. per 100 c.cm. added bilirubin, but if E.S.R. inhibition were directly due to the excess of bilirubin in the plasma the results tabulated in Table I strongly suggest that this amount should be sufficient to cause very marked inhibition.

The result given in Table III shows that added bilirubin has no effect alone, and that if both bile salts and bilirubin are added the resultant inhibition of E.S.R. is that which would be expected had bile salts alone been added. The E.S.R. was estimated after the blood had been kept four hours in the cold in all the bilirubin experiments.

Table III

	Corrected E.S.R. (mm. in 1 hour)
	mm.
Bilirubin 10 mg./100 c.cm.	13
Bilirubin 10 mg./100 c.cm. + bile salt 20 mg./100 c.cm.	7
Bile salt 20 mg./100 c.cm. + 0·1 c.cm. bilirubin solvent	5
Untreated plasma + 0·1 c.cm. bilirubin solvent	11

Discussion

Both Wood and Ziegler have reported a delayed rise in the E.S.R. in infective hepatitis, while Penman in his sanatorium outbreak reports a definite inhibition in the acute stage in one-half of a group of tuberculous patients. Wood does not state how many of his cases were in the pre-icteric phase, but it may safely be assumed that he found fewer cases with a raised E.S.R. in the pre-icteric phase than were found in this series.

Ahlberg (1939) gives the E.S.R. in 36 cases of Weil's disease, in most cases serial weekly figures. In this disease the E.S.R. is raised at all stages, but, as in infective hepatitis, the figures are highest in convalescence. In the first week, using the Westergren technique, he found a mean E.S.R. of 66 mm., which rose steadily to 118 mm. in the fifth week and thereafter slowly fell. In those cases in which figures are given for serum bilirubin there is the same sort of negative relation as in infective hepatitis. Despite the occurrence of haemorrhages anaemia is said not to occur in Weil's disease (Ryle, 1921), and it is quite possible that the relatively low E.S.R. in the acute phase is due to partial inhibition in the early stages, and may well be related to the icterus.

In this series 6 of 8 pre-icteric cases showed a raised E.S.R., and in 40 of 80 cases followed throughout the disease there was a post-icteric rise, while, except in a few mild cases, the E.S.R. was within normal limits in the icteric phase. Further, there was a strong negative correlation between the E.S.R. and the serum bilirubin.

The experiments shown above suggest that an inhibition of the E.S.R. in the icteric phase is more likely due to an increase in the bile salts than in the bilirubin itself, but no figures are available to show whether the amounts of bile salt needed to cause inhibition *in vitro* are likely to be present in the average case of infective hepatitis. Further, one-half of the dose needed to cause inhibition in blood kept for one hour will cause inhibition after 4 hours' storage, and it is possible that if overnight storage were practicable even smaller doses might be effective.

Koster (1937) quoted Bendien, Neuberg, and Snapper (1932) as stating that there is a mobile fraction of non-protein nitrogen, consisting for the most part of polypeptides, which adheres to the proteins when there is a high sedimentation rate and which moves to the erythrocytes when there is a lagging or an artificial decrease caused by oleate or cholic acid. No attempt has been made to repeat this work, and it has not been possible to obtain access to the original paper; but the need for such a transference would explain the period of storage necessary for bile salts to cause inhibition *in vitro* when present in relatively small amounts. Koster does not state whether Bendien found immediate or delayed inhibition from pure cholic acid.

No attempt has been made to exclude the possibility that the changes in the E.S.R. in infective hepatitis may be entirely due to alterations in the plasma proteins. It has, however, been shown that the low sedimentation rate in the acute phase of those cases of infective hepatitis which show a raised E.S.R. in convalescence is closely related to the icterus, and evidence has been put forward suggesting the possibility that an excess of bile salts in the plasma may be responsible.

Summary

In one-half of a series of 80 cases of infective hepatitis the erythrocyte sedimentation rate was raised at some stage of the disease.

In 6 of 8 cases seen in the pre-icteric phase the E.S.R. was raised above 10 mm. in one hour.

It has been shown that in cases in which the E.S.R. is raised there is a strong negative correlation between the height of the E.S.R. and the serum bilirubin.

Evidence has been produced to suggest that an increase in bile salts might cause an inhibition of the E.S.R. in the acute phase of the disease.

NECROSIS OF THE LIVER AND BILATERAL MASSIVE SUPRARENAL HAEMORRHAGE IN THE PUERPERIUM

BY

GLADYS H. DODDS, M.D., F.R.C.S., F.R.C.O.G.

Assistant, Obstetric Unit, University College Hospital; Part-time Obstetrician and Gynaecologist, L.C.C.

Necrosis of the liver during pregnancy or early in the puerperium is not uncommon. Sheehan (1940) described 14 cases in a series of 400 necropsies in Glasgow Maternity Hospital. Haemorrhages in association with liver damage are well recognized, but bilateral massive suprarenal haemorrhage is a rare condition in adults; when it occurs it is most often associated with meningococcal septicaemia. Only two cases (Keele and Keele, 1942; Hall and Hemken, 1936) in which suprarenal haemorrhage was associated with pregnancy are recorded, and in both the condition was unilateral. A recent bilateral case is described below.

Case Report

A primigravida, 34 years old, 38 weeks pregnant, was admitted to hospital in labour on Nov. 24, 1944, at 1.45 a.m. She had attended a private doctor during her ante-natal period. The pregnancy had been normal until Nov. 10, when the B.P. was 130/85, there was slight oedema of the ankles, and a trace of albumin was present in a non-catheter specimen of urine. She was advised to rest at home and to avoid meat and fish.

On Nov. 23 labour started at 7 p.m. and she was admitted to hospital as no beds were available at the nursing home where she had booked. On admission her general condition was good—B.P. 136/86 mm. Hg, a trace of albumin in the urine, pulse 80; there was oedema of the legs up to the knees. Labour progressed normally, and she was delivered spontaneously, at 7 p.m. on Nov. 24, of a 7½-lb. living male child. In the third stage of labour about 14 oz. of blood was lost and the placenta was expressed from the vagina half an hour after delivery of the baby. The pulse rate at the end of labour was 100. The patient vomited once during the second stage of labour while using self-administered trichlorethylene, and once again about 1½ hours after delivery of the placenta.

On Nov. 25 the B.P. was 110/66, and pulse 80. She complained of frontal headache, vomited several times throughout the day, and appeared tired and sleepy. On Nov. 26 she still appeared very lethargic; pulse 82. The sclerotics were slightly yellow. There was no complaint of abdominal pain, and no tenderness was elicited on palpation of the upper part of the abdomen. She vomited once this day—a small amount of brown fluid. She still complained of headache, which was severe enough to keep her awake. A tentative diagnosis of acute yellow atrophy was made. She was given 1,000 c.cm. of 5% glucose-saline intravenously and 10 c.cm. of 10% calcium gluconate. On Nov. 27, at 10 a.m., the patient was still lethargic, but the jaundice had not deepened; pulse 82 a minute. There was some tenderness in the epigastrium but no rigidity. At 11.30 a.m. she became comatose. Respiration was slow and deep. There was no response to stimulation. At 12.30 p.m. she had a slight shivering attack. Her condition improved and she responded to stimulation and answered questions. At 2.45 p.m. her condition had improved considerably. She was alert and asked for drinks and food.

Blood investigations: Protein, 3.33% (albumin 1.76%, globulin 1.47%, A.-G. ratio 1.2:1, fibrinogen 0.10%); urea nitrogen, 78 mg. per 100 c.cm.; N.P.N., 105 mg. per 100 c.cm.; uric acid, 15 mg. per 100 c.cm.; van den Bergh—direct reaction, biphasic; indirect, 3.5 mg. per 100 c.cm.; cholesterol, 83 mg. per 100 c.cm.; R.B.C., 2,350,000; haemoglobin 43%; W.B.C. 26,900 (polymorphs 34%, lymphocytes 65%). Swabs were taken from nose, throat, and vagina for culture—all were negative. Examination of a catheter specimen of urine revealed a trace of albumin, some leucocytes, scanty hyaline casts, no crystals. A growth of enterococci was obtained on culture.

In the evening of the 27th she appeared more alert than at any time since delivery, but now complained of pain in the epigastrium below the right costal region. There was some tenderness on pressure over this area. On Nov. 28 the jaundice had not increased, but the pulse had risen to 100. She was drowsy, and still complained of pain under the right costal margin. At 3.30 p.m. she suddenly became very breathless, then comatose; the pulse deteriorated and she died at 4.50 p.m. The temperature was normal during her stay in hospital.

Post-mortem Findings.—The liver was normal in size; its surface was smooth. It was uniformly yellow and no lobular pattern could be seen. There were no haemorrhages. Microscopical examination revealed massive necrosis, involving the whole of many adjacent lobules; within these necrotic areas there were a few small clusters of surviving liver cells. The kidneys were normal in size; the capsules stripped off easily. The surface of the kidneys was smooth and pale in colour. Degenerative changes were present in the second convoluted tubules and in the loop of Henle. The suprarenals were enlarged to three or four times their normal size. They were deep purplish red in colour. On cutting into them blood spurted out. Microscopical examination showed extravasation of blood in the parenchyma of the cortex and some small areas of focal necrosis with leucocytic infiltration. The capsule was not involved, and for the most part the outer zone of the cortex was normal. Examination of the remainder of the body revealed nothing abnormal. There was no evidence of sepsis.

Discussion

The course of events in the above case can be presumed to have been liver necrosis first, followed later by suprarenal haemorrhage. Haemorrhages are of common occurrence in association with liver damage. An unusual feature was the occurrence of massive haemorrhage into both suprarenal glands. The haemorrhage probably occurred on Nov. 26, when the patient complained of pain in the epigastrium, and accounts for the coma on the 27th. The tendency to haemorrhage in liver necrosis may be associated with low fibrinogen content of the blood.

The liver lesion did not resemble that occurring in obstetric acute yellow atrophy as described by Sheehan. He records "a gross fatty change affecting the entire lobule except a sharply defined rim of normal cells around the portal tracts. The affected cells are bloated by a fine foam of small fatty vacuoles throughout the cytoplasm, the nuclei are normal, and there is an entire absence of necrobiotic change." Stander and Cadden (1934) believe that the fatty degeneration precedes actual necrosis. Glynn and Himsworth (1944) in their report of experimental work on the production of liver necrosis and fibrosis state that by killing the animals at the appropriate time specimens showing acute yellow atrophy, subacute atrophy, necrosis, and fibrosis can be obtained. The liver lesion in this case resembled the liver lesion of chloroform poisoning described by Sheehan and of massive necrosis due to dietary deficiency described by Glynn and Himsworth.

From a clinical aspect three contributory factors were present: (1) the toxaemia, (2) the low-protein diet, and (3) the use of trichlorethylene.

The *toxaemia* was slight and could not account for the severe damage found in the liver cells. It may have been the initial lesion.

Low-protein Diet.—The patient was advised to avoid meat and fish for about two weeks before she was admitted to hospital. As she was not under observation during this period the actual diet is not known. Experimentally, Glynn and Himsworth have produced massive necrosis of the liver by feeding rats on a diet deficient in proteins. It is also worth while noting that before the war of 1914-18 massive necrosis of the liver was a rarity in Central Europe (Strümpell, 1921), while during that war and for some years afterwards its incidence increased owing, it was believed, to the general malnutrition. It was commoner among women than men, largely because of the number of cases occurring in pregnancy. The protein requirements of pregnant women are higher than those of the non-pregnant, particularly because of the needs of the foetus in the later weeks of pregnancy. Digestive disturbance, poor appetite, and sometimes faulty absorption all contribute to the development of deficiency and liver destruction.

Against these two aetiological factors many thousands of women with a greater degree of toxaemia have been treated with a more restricted diet for a longer period without such a catastrophe as occurred in this case happening.

With regard to *trichlorethylene*, the patient had a small quantity of this chlorinated hydrocarbon in the second stage of labour. A Freedman inhaler was used. The amount was not enough to produce unconsciousness. The quantity was not estimated exactly, but it was certainly less than half a drachm. The drug is not very volatile, but it is unlikely that an overdose could have been obtained during inhalation through air. Trichlorethylene has been administered by the closed method to many thousands of cases, and liver damage is not mentioned in these reports (Carden, 1944; Gordon and Shackleton, 1943; Haworth and Duff, 1943; Hewer, 1943; Hunter, 1944). It has been administered through air to a large number of women in labour and, so far, no case of liver damage has been reported (Freedman, 1943; Calvert, 1944). Trichlorethylene is known to produce liver damage much more rarely than chloroform. Liver damage due to trichlorethylene in humans has been reported by Willcox (1931), Roholm (1933), and Vallée and Leclercq (1935), and in animals by Herzberg (1934), Meyer (1929), and Castellino (1932).

At a General Court of the Governors of St. Thomas's Hospital held in London on May 23 an interim report on the reconstruction of the hospital was submitted. St. Thomas's received direct hits on different dates by twelve high-explosive bombs, including one flying bomb, and by a number of incendiaries. The chairman of the reconstruction panel, Mr. H. Winterbotham, said that the interim scheme was designed to cover the period between the end of the war in Europe and the final reconstruction of St. Thomas's. It contemplated the provision of 550 beds in London for in-patients, with facilities for an out-patient department comparable to the pre-war accommodation. Service on this basis was thought to be the minimum needed to maintain the educational standard and the standard of treatment at a proper level. Major Patrick Kinnaird, one of the joint treasurers of the hospital, said that the aim was to have ultimately 1,000 beds compared with the previous maximum of 630. The Lord Mayor of London, who was present at the meeting, emphasized the need to make widely known the prospective deficit of between £30,000 and £40,000, which would have to be made good.

MUMPS MENINGO-ENCEPHALITIS AND ORCHITIS

BY

JAMES P. A. HALCROW, M.B., M.R.C.P.Ed., D.P.H.

AND

IAN WANG, M.B., Ch.B.

(Emergency Medical Service, Scotland)

The following case of mumps with meningo-encephalitis and orchitis, which presents some unusual findings, is considered worthy of record. Meningo-encephalitis occurs occasionally as a sequel of mumps, and cases have been described in which meningo-encephalitis either preceded or was the only manifestation of mumps (Howard, 1919; Bedingfield, 1927). Coe (1945) described a case in which meningitis, orchitis, and arthralgia occurred without parotitis. Harris and Bethell (1938) report one case with meningitis and orchitis but no parotitis. They stress the fact that parotitis is only a common complication of mumps and not an essential feature of the disease. Frankland (1941) describes an epidemic of mumps among soldiers in which meningitis was observed without parotitis or orchitis.

Case Report

A soldier aged 26 was admitted to the medical unit of an E.M.S. hospital on March 25, 1944. His illness began on March 23 with a sharp pain in the right lower abdomen, accompanied by pain in the right testicle and slight frontal headache. The abdominal pain was severe enough to keep him awake all night, and by the next morning it had increased further in intensity. At this time his headache was also worse and he complained of giddiness and drowsiness. These symptoms persisted throughout the day, and nausea and mental confusion also appeared. The temperature during the first two days of his illness varied between 103 and 105.2° F. The pulse rate varied between 82 and 90. The personal and family histories were not relevant.

Examination revealed a well-built man who was flushed and mentally confused. Photophobia was present. All tendon and superficial reflexes were exaggerated. The plantar reflexes were extensor. There was a moderate degree of neck rigidity, and Kernig's sign was positive. Ophthalmoscopic examination revealed a moderate degree of bilateral papilloedema. No other abnormalities were observed in the central nervous system. There was slight tenderness in the right lower quadrant of the abdomen and a mild right-sided orchitis was present. There was no lymphadenopathy or splenomegaly. Clinical examination of the heart and lungs was negative and radiographs of chest and skull revealed no abnormalities. B.P 115/65.

Laboratory Investigations.—The urine contained a trace of albumin but no sugar. Microscopical examination was negative and culture was sterile. The C.S.F. was clear and contained 9 lymphocytes pe c.mm. No excess of globulin was present and the Kahn reactio was negative. Protein, 20 mg. per 100 c.cm.; sugar, 90 mg. pe 100 c.cm.; chlorides, 729 mg. per 100 c.cm. Culture was sterile Culture and animal inoculation for *M. tuberculosis* gave negativ results. Blood culture sterile. Widal reaction, negative. Bloo Wassermann, Kahn, and gonococcal complement-fixation tests al negative. B.S.R. (Westergren) 20 mm. in first hour. Blood coun showed:

	R.B.C.	Hb	W.B.C.	Neutrophils	Lymphs.	Monos.	Basophil
25/3/44			15,000	84%	11%	5%	—
26/3/44	6·25 m.	100%	10,400	78%	14%	7%	1%
3/4/44		100%	8,600	53%	43%	3%	1%

Progress.—By March 26 the orchitis was more severe, and in vie of this and the clinical evidence of meningo-encephalitis, the patien was questioned more closely as to any recent parotid swelling. H then recalled that he had observed slight swelling of the left sid of the face and pain on opening his mouth wide three days befo the onset of orchitis. The facial swelling and pain had disappeare within 24 hours. Although his orchitis had become more sever neck rigidity and Kernig's sign were no longer present; he w mentally much clearer, and headache and photophobia were le pronounced. The plantar responses were still extensor, and in t evening of March 26 he developed quick involuntary twitching o the facial muscles. The next day there was great improvemen temperature was normal, and headache and photophobia had di appeared completely. The plantar reflexes were flexor and t papilloedema was clearing. Thereafter he made an uninterrupt recovery, and by April 5 there was no evidence of orchitis and t papilloedema had gone. A further lumbar puncture was done c

March 28. The C.S.F. was then clear and the cell count 3 lymphocytes per c.mm.; protein, 20 mg. per 100 c.cm.

Apart from the usual nursing measures, the only treatment was a course of sulphadiazine starting on March 24 and finishing on March 27, a total of 21 g. being given.

Commentary

In this case an almost latent parotitis was followed three days later by a fairly severe orchitis, 36 hours after which meningo-encephalitis manifested itself. The unusual features were the low C.S.F. cell count, the rather high sugar, and the presence of papilloedema. The mental confusion, drowsiness, twitching of the facial muscles, and the C.S.F. findings indicated an encephalitis. The clinical evidence of cerebral and meningeal involvement would suggest much more extensive changes in the C.S.F. than were actually found. The cell count was only slightly raised and the protein was normal. In the case described by Coe (1945) the cell count varied from 90 to 100 per c.mm. Harris and Bethell (1938) found 740 cells per c.mm. in the C.S.F. of the case they reported. Synge (1930) describes a case with a C.S.F. cell count of 300 per c.mm. In the five cases reported by Frankland (1941) the C.S.F. cell count varied from 230 to 1,078 per c.mm. None of these authors noted papilloedema in their cases, nor was it mentioned by Rolleston (1932). Price (1942), however, states that papilloedema and even optic atrophy occur as a sequel.

The high initial pyrexia and relative bradycardia found in our case conform to previous case reports in the literature. The parotitis was very mild, and its presence was revealed only by a further close questioning of the patient when it appeared to us that mumps alone could explain the presence of a coincident meningo-encephalitis and orchitis. There was no history of any contact with another case of mumps. There was a high initial polymorphonucleosis, but as the orchitis subsided an absolute lymphocytosis developed, as is usual in mumps.

Recovery was complete and rapid. We do not consider that it was influenced to any extent by the use of sulphadiazine.

Summary

A case of mumps with a mild parotitis and a fairly severe orchitis and meningo-encephalitis is described.

The case is unusual in that the C.S.F. cell count was only slightly raised and, apart from slight increase in sugar, the C.S.F. was otherwise chemically normal.

Papilloedema was a feature of the case, but was not followed by any impairment of vision.

We are indebted to the Department of Health for Scotland and to Dr. J. A. Jenkins, medical superintendent, for permission to publish this report.

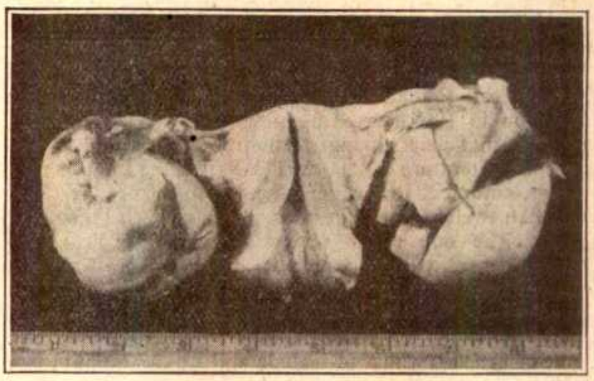
Medical Memoranda

Bilateral Ovarian Dermoid associated with a High Degree of Fertility

The case here recorded is of interest in that torsion of the pedicle of a cyst occupying the pelvis is rare, but the main feature is the high degree of fertility and absence of obstetrical mishaps.

Mrs. A., aged 40, was admitted to hospital on March 1, 1943, complaining of abdominal pain and vomiting. Her menstrual cycle was 28/4, and had always been normal until six weeks before admission, when she had intermenstrual bleeding and "cramps in the stomach." On admission the temperature was 99° and the pulse 88. In the right lower abdomen there was a tumour the size of a full-term foetal head which was movable and cystic and did not seem to be tender, although pressure in a downward direction caused pain. Per vaginam there was a blood-stained discharge; the cervix was badly lacerated and had been pushed forward behind the symphysis by a tense and tender tumour in the pouch of Douglas which had no demonstrable connexion with the abdominal tumour.

During examination under anaesthesia the tumour in the pelvis slipped up into the abdomen, when it became apparent that there were two separate ovarian cysts (see Fig.) and a bulky uterus; on opening the abdomen the pedicle of the cyst on the left, which was the smaller, was found to have rotated through two cycles and the walls were very congested. In view of the history of vaginal haemorrhage and the condition of the cervix, it was considered wiser to remove the uterus along with the cysts. Convalescence was normal.



On being opened both cysts were found to contain a large amount of hair. Microscopical section of the tumours showed them both to be combined dermoid and pseudo-mucinous cystadenomata.

The patient's obstetrical history was as follows: Married at 22. Her first pregnancy ended in an abortion at three months, since when she had had 12 full-term normal deliveries. Each confinement took place at home under the care of a midwife. Her last baby was born 18 months before admission, and she had been a widow for a year.

It is generally accepted that ovarian tumours of this type are of slow growth, and in this case both ovaries must have been the site of these tumours during several of her later pregnancies.

T. G. ROBINSON, M.R.C.O.G.,
Medical Superintendent and Obstetric Surgeon,
South Shields General Hospital.

Cutaneous Anthrax treated with Penicillin

The following case of cutaneous anthrax successfully treated with penicillin may be considered worth recording.

Cpl. A. was admitted on Jan. 12, 1945, complaining of a small blister on the upper half of the left side of his neck which he had noticed for the past 48 hours. He had been feeling cold and off his food all day and had had a rigor, but no headaches, sweating, or constipation. His general condition was good; T. 102.4°, P. 96. The small vesicle on his neck was surrounded by an area of induration, and the adjacent glands at the angle of the jaw were enlarged and tender. Palpation of the abdomen revealed nothing abnormal.

Within 12 hours a circle of vesicles appeared, surrounding a small black centre (see Fig.). Fluid from a vesicle proved that the large Gram-positive organisms of anthrax bacilli were present. No Sclavo's serum was available, so a 5-day course of penicillin was given—15,000 units intramuscularly every 3 hours; a total of 600,000 units. Also 0.6 g. of N.A.B. was injected intravenously, as the clinical efficacy of penicillin in anthrax infection was unknown to us. The pustule was cauterized with pure carbolic acid. The temperature became normal after 24 hours' treatment, and remained so. The black centre became enlarged, and marked adenitis persisted for a week. The patient was discharged 16 days after the onset of his illness, and when seen on Feb. 4 the black scab had nearly separated off and the adenitis had completely subsided. The only possible source of infection was a new woollen scarf which had been obtained from "Comforts" three days previously.

Reviews

YEARBOOK OF SURGERY

The 1944 Yearbook of General Surgery. Edited by Evarts A. Graham, M.D. (Pp. 736; illustrated. 18s. 6d.) Chicago: The Year Book Publishers, Inc.

The American Practical Medicine Year Books, which started publication in 1900, serve the same purpose as our *Medical Annual* in that they summarize the more important articles in the medical literature of the year. Whereas the English volume, however, embraces the whole range of medicine, there are no fewer than twelve American books, one for each branch of the subject. The one under review is the *1944 Yearbook of General Surgery*, which we learn from H. K. Lewis and Co. is already out of print.

The usefulness of such a volume depends entirely upon the success with which the editor chooses, from an immense annual output of articles, which to include and which to omit; it must be allowed that Prof. Evarts A. Graham has done his work well. The book runs to over 700 pages and so summarizes a very large number of articles, far too many for even brief mention in a review; they cover the whole of general surgery. We were interested to find that 16 pages were required to summarize the articles upon pilo-nidal cysts, and equally to notice that this condition has now been dubbed "jeep disease." As would be expected, the great majority of the papers summarized are from American surgical literature, but we note a few, such as one on the crush syndrome, from British journals. A short judicial note by the editor at the end of some of the summaries helps to place certain unorthodox procedures in a correct perspective.

As in this country, the production of the book is controlled by a War Production Board, so that, whereas the greater part is printed on semi-art paper, those sections which contain only line drawings are on a non-glossy surface. This gives the book an uneven appearance, which is, however, necessary in the interests of war economy.

HANDBOOK ON PULMONARY TUBERCULOSIS

Pulmonary Tuberculosis. A Handbook for Students and Practitioners. By R. Y. Keers, M.D., F.R.F.P.S., and B. G. Rigden, M.R.C.S., L.R.C.P. With foreword by F. H. Young, M.D., F.R.C.P. (Pp. 273; profusely illustrated. 17s. 6d., plus 7d. postage.). Edinburgh: E. and S. Livingstone. 1945.

This small book is intended to provide the student and practitioner with a concise and up-to-date account of pulmonary tuberculosis, and achieves its object very well. It is neatly arranged and leads the reader methodically and easily through the subject, avoiding unnecessary detail and emphasizing important points. Though the book contains no original matter, the authors have taken pains to include all recent advances which are of proved value; and many physicians who think they "know their tuberculosis" will find new and interesting knowledge in these very readable pages. Courage and common sense are evident throughout the book, and the authors are not afraid to be dogmatic when the results of experience justify confidence. Few chest clinicians will fail to applaud the decision to give higher priority to the *x* rays than to the physical signs in the diagnosis of phthisis, and the radiological section, with its wealth of excellent illustrations, is particularly valuable. The chapters on treatment are full and accurate, and they are marked by that sympathetic sense of proportion which everyone who has to treat this trying disease should strive to acquire. This modest and well-produced book will fill a real gap in the literature of tuberculosis and will help many to acquire a sound knowledge of the subject.

NEURO-OPHTHALMOLOGY

Few clinical branches of medicine are as precise as ophthalmology and neurology. One would therefore expect a book on the neurological aspects of ophthalmology to be clear in its details and general scope. Unfortunately English literature has produced no such book, though there are several excellent treatises on the subject in German and in French. Dr. D. J. Lyle's *Neuro-Ophthalmology* (Baillière, Tindall and Cox; 58s.) is a brave attempt, but hardly fills the obvious gap. Its outstanding features are its anatomical descriptions and the great number of post-mortem studies. Most of its nineteen chapters begin with a detailed anatomical description, but the clinical sections hardly maintain the high level set in the opening parts. Some of the clinical conditions are reduced to little more than a meaningless mass of names, while others are dealt with discursively and too much in the manner of a clinical lecture. The book is beautifully produced and contains a mass of incidental information.

Notes on Books

The "Careers Books," published by Robert Ross and Co. Ltd., now include a small volume entitled *Medicine*, by Dr. GEORGE LUNTZ. This, in the course of 64 closely printed pages, goes over much of the ground covered before the war in our annual Educational Number. It gives a great deal of detailed information compactly arranged, and some advice on how to prepare for a medical career and how to choose a career after qualification, with notes on postgraduate study and medical research and on higher diplomas, etc. Particulars of each of the universities and schools of medicine in Great Britain and Ireland are summarized in appendices. In his preface Dr. Luntz is particular to point out that in this booklet the medical profession has been taken as it is, and no predictions of the form it will assume have been attempted. The distributors are Rolls House Publishing Co. Ltd., 2, Breams Buildings, E.C.4, and the price is 2s. 6d.

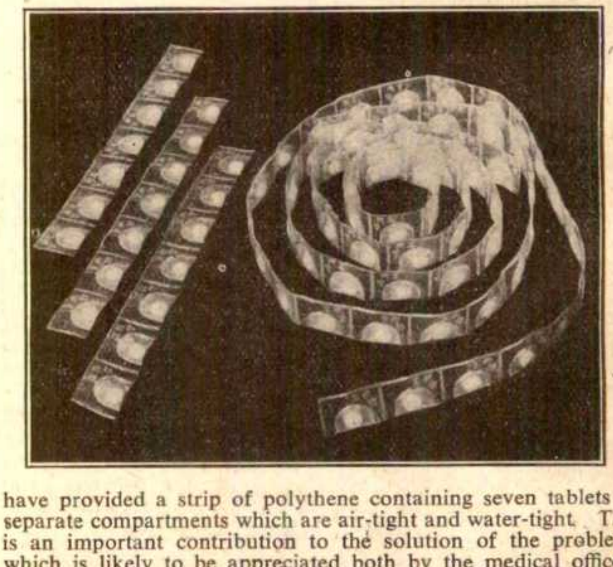
The second edition of *Aids to Fevers for Nurses*, by Miss JOYCE M. WATSON (Baillière, Tindall and Cox; 4s.), the sister tutor of the Park Fever Hospital, L.C.C., contains an excellent account of the subject, which should be in the hands of every nurse.

The official *Medical Register* for 1945 has been published on behalf of the General Medical Council by Constable and Co. (Orange Street, W.C.2) at 21s., post free 22s. The table printed in the introductory section shows that 2,971 names were added last year. New registrations numbered 1,196 in England, 619 in Scotland, 307 in Ireland 320 on the Colonial Register, and 529 on the Foreign Register. The total number of names on the *Register* at the end of last year was 73,646, being 1,764 more than on Dec. 31, 1943. The total number at the end of 1934 was 57,496.

Preparations and Appliances

MEPACRINE PACKED FOR THE TROPICS

One of the minor problems which the Army Medical Services have to face in the Tropics is how to give the soldier tablets of mepacrine, of which he is to take one daily if malaria is to be suppressed. Daily distribution to thousands of men entails great waste of time; yet, if a week's supply is given out at once, the soldier puts the tablets in a pocket where they become dirty or crushed or lost. Imperial Chemical Industries, Ltd., have provided a strip of polythene containing seven tablets i separate compartments which are air-tight and water-tight. Thi is an important contribution to the solution of the problem which is likely to be appreciated both by the medical officer and the individual soldier. With this packing, which can b rolled up into a small space, the week's supply of mepacrin can be kept unsoiled. The machinery for putting the tablet into the sealed compartments of polythene is provided b Genatosan, Ltd.



BRITISH MEDICAL JOURNAL
LONDON
SATURDAY JUNE 2 1945

POLIOMYELITIS IN MALTA

From the time of Italy's declaration of war until late in 1942 Malta was subjected to a remorseless aerial bombardment, sustained with a courage that has now become part of our history. It was a cruel blow that in November, 1942, just at the turn of the tide, the virus of poliomyelitis joined in the attack and produced 483 victims. But there is a happier side to the story, told in this week's *Journal*, for it has resulted in the setting up of a permanent orthopaedic service in the island, and the accounts given in these pages and elsewhere by the band of practitioners, Maltese and British, who directed combined operations against the results of the epidemic, have added many useful bits of knowledge to the already vast literature on this baffling and dangerous malady. The first striking novelty about the Malta outbreak was that infantile paralysis once again justified its name, for of the 426 civilian cases almost all were in children under the age of 5 years and a substantial number under the age of 1 year. After a period of general disturbance lasting for not more than four days, with pyrexia in the majority, the characteristic paralysis appeared. But there were features of this prodromal period which differ from the picture of the disease which has become accepted in recent years. Pain, for example—allowing for the difficulty of determining this in such young subjects—was not an outstanding feature. Stiffness of the back was remarkably infrequent. Delirium and irritability were noted in a comparatively small number. In other words, the usually accepted signs of a stage of irritation of the spinal meninges were not so prominent as in other recent outbreaks. Indeed, the early symptoms, including those in the alimentary and respiratory systems, were remarkably diverse and there was no obvious relation between the mode of onset of the disease and the distribution of the subsequent paralysis. Nearly four-fifths of the patients developed this, either alone or in association with other groups of muscles, in the lower limbs, suggesting a high rate of involvement of the lumbo-sacral region of the cord. An unusual feature in the civilian cases was the presence of facial paralysis in 11%. The treatment adopted is outlined in the two contributions in this issue: it shows once again the remarkable powers of improvisation by the Services when the need arises. The death rate was low among civilians—only 3.5% directly attributed to the disease—but higher in the 57 Service cases, amounting to nearly one-fifth. As usual, respiratory paralysis accounted for nearly all the deaths; and the record of the Service cases contains some valuable comments on the treatment of this serious complication. The complete recovery of 152 and partial recovery of 85 out of the total 426 civilian cases gives some idea of the severity of the outbreak.

Important as these clinical records are, it is the epidemiological side of the story which will, perhaps, have the greater interest. In view of the state of affairs in Malta when the outbreak occurred it is greatly to the credit of Prof. H. J. Seddon and his colleagues that they are able to marshal the facts and present the arguments in such a convincing manner. Their article[1] comes at a time when the new water-borne theory for the spread of the poliomyelitis virus has been gaining wide acceptance, and the Malta outbreak presents great difficulties for the upholders of this theory. Briefly, the facts can be summarized as follows: After a period of relative immunity—with only 61 cases recorded between 1921 and 1941 and none in 1942 up to the outbreak—the disease appeared first in a civilian in Malta on Nov. 15 and in a Service patient on Nov. 27. Thereafter the epidemic continued until the beginning of March, save for a few late sporadic cases. Altogether 426 civilian cases were recorded and 57 in the Services. What makes this epidemic of especial interest, however, is that 42 of the civilian cases occurred in the small neighbouring island of Gozo. All of these patients (except one—a refugee) were inhabitants of Gozo; the first case occurred on Nov. 21, half-way between the first civilian and the first Service case in Malta; and the distribution of the cases on Gozo failed to conform to a pattern whereby the early cases were in the towns nearest to the main island. In fact, to put the crucial position of Gozo in its full colours, apart from human carriers the only possible common factor that might be of significance was dried milk, distributed on both islands. But the dried-milk hypothesis is dismissed as fantastic, for it would involve assuming that certain batches of milk from well-known firms had become contaminated and that these batches had happened to reach almost every part of Malta and Gozo. Moreover, consumption of dried milk had begun well before the epidemic started, and continued for long after it was over.

With these facts about Gozo in mind, the remaining hypotheses examined by Seddon and his colleagues can be briefly dismissed. Excremental spread has attracted much attention in the last few years in association with the water-borne theory. The sanitary conditions of Malta were in a serious state owing to the bombardment. Moreover, with a threat of famine, the Government had reluctantly given permission for the use of sewage for farming purposes. (No such measures were sanctioned on Gozo, although excrement had long been used for manure there despite the vigilance of sanitary inspectors.) But, whereas the civilian population of Malta might have been infected through contaminated vegetables, it is pointed out that the kitchen technique of the Army and Royal Air Force would almost certainly have "closed this possible source of the virus." The position of milk has already been examined. Water supplies were not unnaturally complicated, and, indeed, from the distribution of the cases occurring in the first two weeks of the outbreak it would be necessary to postulate the simultaneous contamination of at least four and at most six separate supplies in Malta, to say nothing of the separate supply on Gozo. The case for flies as vectors of the virus is not strong. The rate of development of the disease was too rapid; it was at its height at a period when flies were less numerous than at any other time of the year, and, as already mentioned, if infected flies flew to Gozo it is strange that the first cases did not appear in the towns nearest to Malta. It is concluded that the epidemic was mainly spread by nasopharyngeal droplets and what are termed "droplet nuclei." The age distribution of the civilian and Service cases suggests that the causal strain of virus must have differed only slightly from the usual endemic Maltese strain, for its successful attacks were confined to the more susceptible civilian age groups. On the other hand, the high incidence and severity of the disease in the Service cases suggest that the strain differed much from that usually endemic in the British Isles. There had been an influx of some 200 airmen in October and November, 1942, and it is conceivable that there were some carriers among them; but the civilian outbreak started nearly two weeks before the first cases in the Services; it was three weeks before an airman succumbed, and the civilian outbreak did not occur in places where there were large concentrations of Royal Air Force personnel. There is thus no real evidence that the infection came from without. Indeed, with the Gozo outbreak to be accounted for, the presence of an indigenous carrier or carriers is strong, and the predisposing factors of overcrowding, physical and nervous fatigue, and an inadequate dietary were all present to help in the spread of what appears to have been essentially an epidemic of infection of the respiratory type.

[1] *Quart. J. Med.*, 1945, 14, 1.

Howe, Bodian, and Wenner[2] have recently extended their observations on the presence of the poliomyelitis virus in the human oropharynx, recovering it from swabs in 43% of a series of 23 cases during the first three days of illness but never after the third day. These workers do not discuss the presence of the virus during the prodromal period, but other investigators suggest a total period of maximal infectivity of about a week, distributed more or less equally before and after the onset of paralysis. Thus, however the first cases occurred, subsequent spread by droplets, analogous with the spread of cerebrospinal fever, seems the most likely explanation of the Malta epidemic. This almost old-fashioned view of spread, and the high incidence of truly infantile cases with a striking absence of the "spine sign" in the prodromal period, are the outstanding features of a tragic outbreak and take the picture of the disease back almost a generation. Because of this fascinating reversion alone the Malta cases will be studied with great interest. For the courage and enthusiasm with which the epidemic was fought by all concerned, from the Governor, Lord Gort, downwards, it adds yet another distinction to the records of this remarkable island.

DISABILITY AFTER CLOSED HEAD INJURY

When a man has had a closed head injury he is more likely to find himself handicapped through defects in his memory, intellectual capacity, and ability to concentrate, or through personality changes such as moodiness and irritability, than by discrete disturbances of bodily function. The injuries which result in cranial nerve damage or in local destruction of brain tissue with consequent motor or sensory defect are usually the more severe, or are associated with a fracture of the skull or some other complication. In wartime we have come to regard these complicated injuries as the rule, for gunshot wounds penetrating the brain have produced all manner of disabilities which are not commonly seen in the simple closed head injuries of peacetime. Denny-Brown[1] has recently emphasized the difference in the prognosis of head injuries in peace and war by describing a study of the symptoms which persisted in a large group of civilian patients in the Boston City Hospital who had suffered accidental head injuries. Out of 430 consecutive admissions he selected 200 patients between 15 and 54 years of age who had been normal citizens before the accident. Most of these patients had had mild head injuries, but they represented a sample of the usual run of head injuries admitted to hospital in peacetime. Symptoms persisted for more than six months after injury in over half the cases, although there were only 27 of the 200 patients with a post-traumatic amnesia of longer than 12 hours. The most frequent symptoms were headaches, dizziness, and disturbances of feeling or behaviour grouped together as "psychiatric." Other, physical, symptoms were present in only 8%. In spite of these symptoms 80% who were not otherwise prevented from returning to full employment did so within two months of leaving hospital. The mental symptoms related to anxiety caused the greatest delay in returning to work Analysing the factors which may have been responsible for the persistence of these mental symptoms, Denny-Brown found that the severity of the injury and the environmenta factors, such as occupational or home worries or concern for compensation, were mainly to blame. He considered intellectual disorder and personality change as relatively unimportant, and concluded that the environment in which convalescence took place was even more significant tha the severity of the injury.

These conclusions are of importance, for they affect th whole approach to the prognosis and management in case of head injury. Whether personality change or intellectua defect is recognized by examination after injury may wel depend upon the delicacy of the methods employed. Th best method is, of course, to expose the subject to stress an to observe his response. The labourer may show no intel lectual impairment to testing or at his work, but the profes sional man, normal to testing, will later describe evidence of intellectual defect which he had recognized in his wor at a level of thought never attained by the labourer. S with personality testing. An intelligent observer who kne the patient intimately before the accident will describ changes in personality in response to stress which mu have been a direct result of the injury, but which were n apparent in the quiet of a hospital. Disturbances of intellect and of personality of this kind cannot be demonstrated by ordinary methods of testing, but the rare patient whose activities are on a high enough plane and who can be honestly introspective will convince the observer of their reality. Though they usually coexist, a change in personality may be appreciated after intellectual recovery seems to be complete. Many excellent studies of this subject have been made in this country. Symonds[2] has dealt with the mechanism of the post-traumatic cerebral state, and Neustatter[3] has demonstrated the difficulty in deciding whether this syndrome is physiogenic or psychogenic. Aubrey Lewis[4] has found it impossible to distinguish the syndrome of a post-traumatic cerebral state from an anxiety state of psychological origin. At the Royal Society of Medicine Patterson, Reynell, and Kremer[5] recently discussed various aspects of the development of post-traumatic personality disorders, and made it clear that disturbances of mild degree may have serious consequences. Schaller[6] has tried to separate the physiogenic from the psychogenic syndromes upon the basis of symptoms, but Denny-Brown[7] has criticized this attempt, and there must be wide agreement with him. It seems, however, that in emphasizing the environmental causes for the persistence of neurotic symptoms after injury Denny-Brown has erred to the other extreme. It is quite true that some patients develop a neurosis out of all proportion to the severity of the head injury as a result of outside factors, which include compensation, head-consciousness, and other causes of anxiety. It is equally true that intellectual disorder may be unassociated with severe disturbances of affect. In the great majority of cases a man who is handicapped by intellectual defect or personality disorder after an injury is unable to withstand the stress of his environment incidental to his injury because of this very handicap. If the stress is slight or the handicap small he may escape with a short illness, but a defect of intellect or personality well enough marked to be measured or recognized in the ward will be a profound handicap to most people. It is not true to say that, because it cannot be demonstrated by such means, it is not present. The patient's future failure to overcome his difficulties as he did before the injury is evidence of its existence. This view does not exonerate environmental factors; it merely relates the psychogenic to the physiogenic causes of the disorder. The possibility of gain from the injury is still a great deterrent to recovery.

---

[1] *J. Amer. med. Ass.*, 1945, 127, 429.

The head injuries of war do not differ in this respect from those of peace. The psychological handicaps are different in some ways; the relative incidence of focal and general brain damage is different; but in each case the likelihood of persistent post-traumatic symptoms, particularly mental symptoms, depends on the kind of man who is injured, the kind of injury he has received, and the kind of psychological stress with which he has to contend. The effect of extraneous psychological factors will be influenced by the handicaps in personality and intellect which he had before the injury, as well as those found afterwards.

FIBROSITIS

Increasing attention is being given to the problem of fibrositis, and the scepticism often expressed in the past as to its being a definite pathological entity is giving way under the pressure of such facts as those presented recently by Copeman and Ackerman.[1] In spite of the difficulties imposed by active service conditions they have supported their clinical observations by research into the anatomy and pathology of fibrositis, by both necropsy and biopsy. Attention has been concentrated for a long time upon the painful nodules often met with in fibrositis. The histological characters were fully described by Stockman, though they have been sometimes described as structures found by the fingers of the physician but not by the surgeon's scalpel. Clinicians were reluctant to ascribe the pain and stiffness of fibrositis to these nodules, or to believe that organized fibrous structures could be broken down and the symptoms relieved by heavy massage.

The work of Sir Thomas Lewis on referred pain, amplified by Kellgren, who demonstrated the relation between localized tender spots and referred sciatic pain, aroused fresh interest, and Elliott threw further light on the matter by demonstrating that these spots were associated with areas of increased excitability in the corresponding segment of the spinal cord. Now Copeman and Ackerman have shown that these "trigger points" are associated with certain areas of the back where pink fatty tissue of a particular type lies between the superficial and the deep fascia. The distribution of this fat, which they term "basic fat," forms a pattern found to be constant in many bodies examined post mortem, even in the most emaciated subjects, and coinciding with the distribution of tender spots demonstrated clinically. This fat was also found in close association with tendons, forming their sheaths, and also where the fascia was split to invest a muscle. The fat is vascular and liable to become oedematous and congested, possibly under the influence of meteorological and other influences, and may thus narrow the lumen of the tendon sheaths and cause stiffness and pain. A similar effect may arise in other situations, and this furnishes a far more convincing explanation of the characteristic symptoms of acute lumbago than many other theories. This underlying fat, when congested and swollen, tends to bulge through any weak spots or deficiencies in the enveloping fibrous layers or through the foramina which give passage to the nerves and blood vessels; these herniations form tender nodules and trigger points.

The authors describe various types of herniation—non-pedunculated, pedunculated, and foraminal—and suggest that they may be the seat of chronic strangulation and become hard fibrous nodules: they demonstrated strangulation at operation but not the hard nodules. Treatment by operation or by needling gave striking results in many cases. Further investigations along these lines and verification by other workers will be awaited with interest, but it is evident that an important advance has been made. It may also be observed that service in the R.A.M.C. under war conditions is no bar to research into the problems which beset the civilian practitioner if the thirst for knowledge is present.

PA PING OR BARIUM POISONING

Huang[2] has recently described twelve cases of "Pa Ping," a name familiar to the general population in Szechuen for a transient paralysis similar to familial periodical paralysis. Szechuen is a large salt-producing area, and barium chloride in concentrations as high as 25.69% has been found as an impurity. All the cases described by Huang were in males, but Du and Dung[3] have observed the disease in females. The symptoms, which usually came on soon after a meal, consisted of nausea, vomiting, diarrhoea, sometimes associated with abdominal pain, abnormal sensation of the skin, and flaccid paralysis of the limbs, first developing in the lower and then gradually affecting the upper. The pupil reaction was always preserved and the mind remained clear. The blood pressure was raised, the pulse rate and body temperature lowered. All the cases described by Huang recovered completely in one to three days, leaving no residual symptoms or signs; but Du and Dung[4] state that the mortality ranges from 5 to 10%. Allen[5] describes a necropsy of one case: there were parenchymatous degeneration and congestion of the liver, heavy congestion in the kidneys with parenchymatous degeneration of the tubules, and eosinophilic infiltration of the mucosa and submucosa of the duodenum, with a patch of hyaline degeneration in one muscle fibre; in the spinal column there was a chromatolysis of nerve cells in Clarke's column; there was also an endothelial swelling of the blood vessels, and a questionable increase in the microglia in the grey matter; congestion was most marked in the nerve roots.

[2] *Chin. med. J.*, 1943, **61**, 305.

Chou and Chin[6] and Ku, Yen, and Li,[7] believing that barium was the cause of this paralytic syndrome, investigated the pharmacology and toxicology of the soluble barium compounds by means of animal experiments. They administered isotonic barium chloride solution to fasting dogs by gastric tube, and by intraperitoneal, intravenous, intramuscular, and intrathecal injection. When the drug was given by mouth they observed symptoms similar to those occurring in Pa Ping disease. Salivation, vomiting, and diarrhoea were conspicuous, and neuromuscular symptoms such as twitching, tremor, and motor weakness appeared in most cases, followed by paralysis of the skeletal muscles in severe cases. After intravenous injection cardio-respiratory symptoms were more prominent, and a minute amount of barium in the cerebrospinal fluid caused convulsions. Serum concentrations of 2.2 mg. per 100 c.cm. were obtained after ingestion of the barium by mouth, but concentrations of over 5 mg. per 100 c.cm. occurred after parenteral injection. Half the barium was removed from the blood stream in 15 to 30 minutes, and three-quarters within two hours. Although the soluble barium salt may be precipitated rapidly in the gut by inorganic sulphate—and barium sulphate is generally used for opaque meals by radiologists—such precipitation does not occur in the blood stream: here the barium probably forms barium proteinate in the serum.

Huang, thinking that the symptoms of Pa Ping were caused by a low serum potassium, treated two cases with intravenous injections of 80 c.cm. and 145 c.cm. of a 5% potassium citrate solution. In both cases rapid and complete recovery took place immediately after the injections, but unfortunately they did not estimate the serum potassium before treatment. There seems no doubt, however, that the immediate cause of this particular syndrome is the taking of salt or water containing barium chloride as an impurity. The logical treatment, therefore, appeared to be that described by Allen—giving sodium or magnesium sulphate in sufficient doses to precipitate the barium as insoluble sulphate. If the disease is suspected treatment should be immediate, since the absorption of barium chloride is extremely rapid. Now that the cause of the disease is recognized, however, prevention should be accomplished by chemical analysis of brine at the well-head of all salt wells. It seems highly probable that there is a relation between Pa Ping and familial periodic paralysis, and further research should be undertaken to discover whether soluble barium salts in some way disturb the potassium equilibrium in the body. Eight years ago, in some observations on a young man suffering from familial periodic paralysis, Aitken, Allott, Castleden, and Walker[8] found that during the paralytic attacks the serum potassium level would fall from a normal of 20 mg. per 100 c.cm. to less than 10 mg.; 12 mg. per 100 c.cm. appeared to be a critical level below which paralysis developed. They induced attacks by administering large amounts of glucose by mouth, by the injection of insulin, and especially by combined injection of insulin and ingestion of glucose. Potassium chloride by mouth raised the level of potassium in the serum and abolished the paralysis. Aitken and his colleagues concluded that the fall in serum potassium concentration was associated with the passage of glucose from the blood into the tissues, and that abnormal lowering of the potassium level either blocked neuromuscular transmission or inhibited the contractile response in the affected muscles.

ANTIBIOTICS FROM PLANTS

The success of penicillin has led to detailed search for similar products among fungi and soil bacteria, and many substances with antibacterial action have already been discovered. The latest extension of this work is the search for antibacterial substances in the higher plants. The first report on this subject was given by Osborn[9] from the School of Pathology at Oxford. He examined 2,300 species of plants belonging to 166 families by methods similar to those used in estimating penicillin, and he found substances which would inhibit the growth of *Bact. coli* and *Staph. aureus* to occur in 63 different genera. The most active substances were obtained from plants of the Ranunculaceae family, especially anemone, clematis, Christmas rose, and buttercup. The field has been developed further by Lucas and Lewis.[10] They were guided in their search by the clues (1) that the tips of growing roots survive and expand in the presence of innumerable micro-organisms, and (2) that plant drugs have been used all over the world as folk remedies. Extracts were made from various plants and tested for their power to produce a zone of inhibition on agar plates inoculated with *Staph aureus*, with *Bact. coli*, or with certain bacteria pathogenic to plants. Antibacterial principles have been discovered in a variety of plants, though they vary greatly in their potency and distribution. They have been detected in the leaves of Scotch thistles, of verbascum, and of peony, and in the fruits of members of the rose, saxifrage, and other families. In particular a species of honeysuckle, *Lonicera tatarica*, has been found to contain a potent principle which inhibits the growth of *Staph. aureus* and of *Bact. coli*, and another which suppresses coliform bacilli but not Gram-positive organisms. The principles are soluble in water and are stable to heat.

From the therapeutic aspect it must be remembered that the presence of antibacterial activity is only half the picture, and that the absence of undue toxicity is equally important. It is this lack of toxicity which has made penicillin so much superior to the other antibiotic substances so far discovered. But whatever the ultimate findings about these particular preparations, it is clear that the researches in question open up a new field which may well prove to be very fruitful. Moreover, the implications of these results are not restricted to medicine, but may concern wide fields of general biology.

DIET FOR MALNOURISHED PRISONERS OF WAR

BY

SHEILA KENNY, M.D.

A brief record has been made of 24 recently released British P.O.W.s admitted to hospital in this country for malnutrition and other conditions. The majority had done a long forced march and had been liberated only for periods varying from 2 to 7 days. Before admission 21 had suffered from severe diarrhoea, either during the march or after their liberation, on a sudden return to a full diet.

On receiving the first group one was appalled by their emaciation. However, since enteritis was also an urgent symptom, it was felt that caution in feeding was necessary. No literature on the subject of malnutrition was immediately available, but a decision about the diet had to be made quickly. The problem was to find one which, while suitable for the intestinal tract of men suffering from prolonged starvation, would also restore the depleted body tissues. A simple method was adopted which has, on the whole, proved satisfactory.

State on Admission

Mental.—Most of the patients were still in a state of extreme elation; if some were not, it was because they were too exhausted physically. This state has gradually subsided to one of remarkable contentment while awaiting fitness for discharge.

Physical.—Apart from the first group (see Table) and the general emaciation, the bodily condition was fairly good. The clinical anaemia was not in proportion to the emaciation, and this finding was supported by the haemoglobin estimations. All the patients were clean, but one was recovering from very severe generalized louse-bites. There were no infectious skin diseases. Mild pyrexia was found in all the active cases of enteritis. Three patients were suffering from septic ulcers of the heels, the result of blisters occurring during the forced march. The condition of the teeth was generally bad. (No dental treatment had been available during captivity.) The abdomen was distended in nearly all cases, even in those not suffering from enteritis on admission. The active cases of enteritis were having loose watery motions—2 to 10 a day.

Treatment

It was decided to put the patients on a third-week gastric diet (modified Lenhartz), with the addition of three eggs daily, and to increase or decrease this diet according to the patient's progress. Half the adult dose of vitamins, cod-liver oil and iron was considered advisable for the first week, with an increase to the adult dose by the second week. Fersolate tablets seemed to be well tolerated. Plentiful supplies of oranges were available. Mist. opii, catech., et cret. was given two-hourly to the first batch of cases suffering from enteritis; but as this was ineffective in the severe cases—for which reduction from the third-week diet was necessary—it appears that the dietary treatment alone was responsible for clearing the enteritis in the milder cases.

Observations

Patient No. 3 was so ill on admission that it was obvious he could not be put on third-week gastric diet. He therefore received glucose fluids only, by mouth, and 1,000 c.cm. of intravenous plasma, followed by 1,000 c.cm. of glucose-saline in 29 hours. The result was dramatic; within 36 hours of starting parenteral treatment he asked for a poached egg. This was allowed with some misgivings, fortunately unfounded. From then on he was put on a third-week gastric diet, and finally reached sixth-week diet at the same time as the non-enteritic patients. In two other cases also—1 and 4—parenteral fluids were necessary, although these patients were kept on third-week gastric diet before this was realized. Case 1 had prolonged diarrhoea, and Case 4 repeated vomiting. They were both given glucose fluids by mouth, and 1,000 c.cm. of intravenous plasma. In each of these cases also the result was dramatic. (Case 4, now here 3½ weeks, has gained 10 lb. in 10 days: this satisfactory improvement cannot be shown in the Table. Case 1 has been here only 2 weeks.)

Details of Cases

* 1 denotes enteritis during the forced march; 2, enteritis during the period between liberation and dietary treatment; 3, enteritis on beginning dietary treatment; 4, enteritis after beginning dietary treatment.

† These cases were fit to be discharged from hospital before they had been here two weeks.

Apart from these three cases little difficulty has been encountered. The satisfactory cases were kept on third-week gastric diet for periods of from 48 to 72 hours, and then advanced to fourth-week and so on, slowly, until sixth-week diet, with meat, was reached (this stage was reached within 12 days by all except Cases 1, 2, and 4). Case 6 had developed vomiting—considered due to sweets given him by a neighbouring patient—but he also reached the sixth-week stage on the twelfth day.

The most marked gains in weight have been in the second group. This was to be expected, because the third group had lost relatively less weight, and the first group, besides delay in reaching a fuller diet, were nearly all suffering from some active disease. The weight-recording of Case 6 is interesting. On admission this man had severe painless oedema of legs and feet, present since the end of the march—i.e., about three weeks before admission. (Urine N.A.D.) The diagnosis of wet beriberi was considered. Unfortunately, the vitamin B_1 content of the urine was not estimated. The oedema diminished rapidly while on third-week diet with large intramuscular doses of aneurin. The weight-recordings for this patient are as follows: on admission, 10 st. 4 lb.; one week later, 9 st. 7 lb.; two weeks later, 10 st. 5 lb.; three weeks later, 11 st. 2½ lb.

It is highly significant that in such a small group of very recently liberated prisoners of war there are just over 20% of cases of pulmonary tuberculosis. Three of the 5 cases were unsuspected when first admitted here. There is likely to be a high percentage of tuberculosis among our returning prisoners—first, because of the terrible degree of malnutrition present; and, secondly, because of the unhygienic conditions of the prison camps. Would it therefore not be wise to keep at least the definitely malnourished men under observation for 6 to 12 months, and *x*-ray their chests at two- or three-monthly intervals?

Conclusions

All cases suffering from malnutrition are liable to develop diarrhoea if put too soon on a full diet. The intestinal mucosa in malnutrition is often oedematous, and, even when it is not, it is reasonable to assume that the gastro-intestinal tract needs "re-education" in the digestion of a normal diet. In extreme malnutrition, body reserves may be so exhausted that not enough are left to supply even the enzymes necessary for digestion. In the less severe cases of malnutrition in which, however, enteritis is already present, milk-feeding might be regarded as an ideal method of "digestion re-education," if such were the only aim in the treatment. But another very important aim is to restore the depleted body tissues. Third-week gastric diet, including three eggs daily, provides an easily digested diet for the first two days' treatment, and is a safe means of observing the patient's digestive powers. From this starting-point advance can be made along the later stages of gastric diet, adding more protein if necessary. That patients do make a satisfactory gain in weight on such a diet is shown by results obtained in 14 days, 12 of which were spent on this diet.

The more severe cases of malnutrition should be put on parenteral fluids without delay. Plasma, although not regarded as an ideal substance for parenteral nutrition, has proved very satisfactory in three fairly severe cases of malnutrition, and may well be used temporarily when supplies of protein hydrolysates are not available.

Summary

Twenty-one cases of malnutrition in recently liberated prisoners of war have been treated by first putting them on third-week gastric diet with additional protein, and then increasing the diet slowly until it is a normal one; this stage was reached on the twelfth day after admission. During the first two weeks the majority of the patients showed a satisfactory increase in weight, and the enteritis present in some cases on admission cleared rapidly.

Three severe cases were given intravenous plasma until fit to be treated like the milder cases.

Just over 20% of the cases have active tuberculosis; hence the advisability of keeping all malnourished prisoners of war under observation for developing tuberculosis for some time after discharge from hospital.

My thanks are due to the medical superintendent for permission to publish these results; to Dr. I. Davies and Dr. H. Evans for their advice; and to the staff of the Whitchurch E.M.S. Hospital for their co-operation in treating the cases.

IMPAIRED WORKERS IN INDUSTRY

AMERICAN EXPERIENCE AND SUCCESSES

BY

HERMANN LEVY

"Physically impaired workers employed in factories are just as efficient in the jobs they hold as their unimpaired fellow workers." This is the conclusion which official American investigators have arrived at after a careful and detailed study of *Impaired Workers in Industry*,* covering 300 establishments with 63,382 impaired workers. The statement conforms to the general experience in this country of the results of methodical and comprehensive rehabilitation of injured workers and their resettlement in industry. It may be taken as another hopeful indication that the Disabled Persons (Employment) Act is a step in the right direction.

The U.S. is, in general, much advanced in the art of special research in the economic and social field. Investigators in that country know well how to make the best use of statistical methods. The present inquiry provides a good many interesting details of a problem whose complexity should not be underestimated. Of the disabled workers covered by it 87% were reported to be just as efficient as the unimpaired doing similar work, and the 8% reported as more efficient outweighed even the 5% reported as less efficient.

Absenteeism may be regarded as a part of inefficiency. The handicapped worker in many cases finds it more difficult to get a job, but once he has it he is anxious to keep it and to prove to himself and to others that he is as good as, or better than, his fellow workers. It is, therefore, not surprising, indeed, it is highly gratifying, that in the matter of absenteeism the physically handicapped had a better record than the normal worker. Of the former, 44% were reported as having an absentee record no worse than that of their fellow workers, while 49% had better records; only 7% were absent more than the normal worker.

Accident Proneness

In addition to occupational efficiency and absenteeism there is the problem of the position of the disabled in relation to accidents. Employers have at times been reluctant to employ partially disabled workers, fearing that their handicap might involve the risk of further, possibly even more serious, accidents. Latest experience has indicated, however, that such workers may, through being more careful than their fellows, show a smaller injury risk. In the American inquiry only 2% of the firms stated that some of the employees attempted to obtain compensation for the aggravation of an old injury. As to new accidents the physically handicapped generally experienced fewer injuries; in 38% the accident rate was no higher than in the workers without disabilities and in 51% it was lower; in 11% only was it higher. Similarly, changes of job were less frequent among the disabled.

These results lead to another question which still awaits some clarification. We know through the investigations of the Medical Research Council and the Industrial Health Research Board that generally a relatively small percentage of workers in an establishment encounter a relatively high percentage of accidents. This accident proneness has lately been reaffirmed by another American investigation, which showed that in shipyards 23,188 injuries were received by 8,599 individuals, and that more than half of the workers reported two or more injuries in a year; about 20% of the workers experienced 50% of all reported injuries. Does this definite tendency to accident proneness indicate that injured workers are more liable to sustain another injury than normal workers?

The American report on *Impaired Workers in Industry* seems to supply an answer to this question. The rehabilitated worker is not a person who can be fitted into any industrial job. The utmost attention must be paid to his handicap, to the history of his case, and to a series of psychological and sociological factors if the advantages to be derived from his restored efficiency are not to be lost. The Department of Health for Scotland, in a report on *Health and Industrial Efficiency* in 1943, said that persons invalided out of the Forces as medically unfit for further service "fared badly" socially, medically, and "in relation to work" when left to themselves. The American report, in the statement quoted at the beginning of this article, cautiously speaks of "the jobs they hold." This means that all the good features of efficiency, reduced absenteeism, and fewer accidents presuppose that the impaired worker finds the right job and the right kind of occupation.

Selective Employment

The report makes it clear that the crux of the problem is not just placing the disabled worker in employment but placing him in a suitable job. It will be noted with interest in Britain that of the industrial firms concerned only 7% reported that in their establishments there was no physical examination of the disabled before employment nor had an analysis been made of the jobs suitable for them; 17% reported that applicants were examined physically before being employed, but were not placed on the basis of job analyses; 15% reported job analyses only; and 61% reported both. The report shows that many firms, big and small, know that it is now common practice to examine an applicant and to study the physical requirements for each job so that he may be placed most advantageously from his own and the employer's point of view. We have heard much in Britain of late about the higher output per man hour of many American industries. It may well be that this selective placing in industry, which so greatly benefits the disabled worker as well, plays an important part in this, quite as much as the introduction of rationalized machinery. Some small firms consider that the increased personnel required would make this procedure too costly for them, but it is suggested in the report that such establishments do not require a full-time medical examiner.

---

* The investigation was prepared for the U.S. Bureau of Labor Statistics in the Bureau's Division of Industrial Hazards by Clarence A. Trump and Frances J. Montgomery, see *Monthly Labor Review*, October, 1944.

Recognition of the importance of and the need for careful selection of employment for disabled persons opens a wide field of activity for voluntary social service, but it is a service which also pays the employer. The advantages which some firms derive from this selection were recorded. A large aircraft corporation employing 900 physically impaired workers noted that "deaf persons have been found very useful in the riveting departments. Because of the noise involved it has been found that their work is generally better than that of persons with normal hearing. This applies to efficiency on the job, absenteeism, and labour turnover. Blind persons have been used successfully in salvaging operations, mainly in sorting the rivets." Sometimes the almost unbelievable happened: devices such as a mirror for a one-armed operator were so successful that the firm concluded that they were equally helpful to normal operators.

It is evident that employers have a novel, but most encouraging task before them if they will study and adopt the teachings of such sample tests as this. Some firms, after considerable job analyses, reported that they had reached their limit in the employment of rehabilitated workers. Many employers seem to think that these workers are only useful on tedious or repetitive jobs or as clerks and watchmen. Perhaps more thorough analyses, the report observes, of physical requirements would reveal additional posts suitable for them. This conforms with the views long held by one of the foremost surgeons in this country, Mr. E. H. Griffiths; but it is highly desirable that the procedure should not be limited to cases of fracture but should be extended to persons suffering any kind of injury or serious disablement, a point which is not yet fully recognized in this country, where rehabilitation is far too much identified with the task of the surgeon only.

In Canada, not unlike the U.S.A., the re-employment efforts of different industries—metal trades, lumbering, and textiles—have not been uniform; there has been more progress and, indeed, willingness in some than in others. It is interesting to note that the Workmen's Compensation Board in Toronto does not hesitate to point out with reference to the re-employment figures of various trades that one industry should not stay behind another in what the board calls "a patriotic duty" (see *Rehabilitation*, published by the Industrial Accident Prevention Associations, 1943). Societies devoted to voluntary social service can surely inspire their employer-members with the desire to help in the re-employment of the disabled worker and thereby lighten the burden placed on the shoulders of "officialdom" by the future social security legislation.

As to the placing of impaired workers in this country, the necessity for job-analysis, so successfully started in the U.S.A., cannot be over-emphasized. Employers will need it (1) in connexion with their liability under the Reinstatement in Civil Employment Act to reinstate workers in their former occupation or in the most favourable alternative occupation that is reasonable and practicable; and (2) in connexion with their liability under the Disabled Persons (Employment) Act to place a certain quota of disabled persons. As the Industrial Welfare Society discloses in a recent publication on "Reinstatement," firms have asked for a standard schedule of occupations which will help them in the classification of jobs suitable for various disabled persons. It is disconcerting that the Industrial Welfare Society has to inform its members that the only schedule of that kind as yet available is one issued by the U.S. Government; this may be consulted at the library of the American Embassy in London.

U.N.R.R.A.'s MEDICAL AID TO CHINA

Even before the Japanese invaded China her public health services were inadequate for the population, and there was a shortage of doctors, nurses, medicines, and hospital equipment. Now, after eight years of war, there is roughly one doctor for every 40,000 of the population and one hospital bed for every 10,000. Up to 40% of the hospitals have been destroyed or looted, sewage disposal plants have been wrecked, and water supplies contaminated. The danger to national health will be even greater when millions of Chinese who have been driven from their homes start to return. China has, however, a medical relief programme, but it is estimated that she will have to train some 35,000 technicians in the next four years to administer it. In the meantime U.N.R.R.A. has come to her help and is recruiting surgeons, physicians, dentists, nurses, sanitary engineers, maternity and infant welfare specialists, tuberculosis specialists, hospital and public health administrators, among others, for work in China. The first to go there will be men with general medical experience; specialists will follow later when training programmes are set up. Special medical supplies urgently needed by the Chinese universities, including books for teaching purposes, have already been sent, part of the passage being by air. Arrangements have also been made to send 30 medical and health experts to train personnel in the medical centres to be established by the Chinese Government. U.N.R.R.A. will dispatch 90,000 lb. of medical equipment for these centres in the coming months. The Chinese Government plans to establish in the near future training centres in Chungking and Chengtu, and later in Kweiyang. Other centres will be set up in Nanking and Peiping when these cities are freed. Short intensive courses averaging from six to eighteen months will be given to people recruited in China by the Chinese Government. There are to be refresher courses for doctors, public health courses for those who have recently graduated and for nurses who have not had public health experience, technical courses for partly qualified doctors and nurses, and training courses for attendants, nurses, and midwives.

Shipping space has been made available to U.N.R.R.A. to carry the supplies to India, and Dr. Tingfu F. Tsiang, Director of the Chinese Relief and Rehabilitation Administration, has arranged for them to be carried on to China by air.

Medico-Legal

PRISON FOR PRETENDING TO BE A DOCTOR

At Manchester Assizes on May 11 Mrs. Doreen Warren, of Heswell, near Liverpool, pleaded not guilty to the charge of providing a false declaration in order to be registered as a medical practitioner.

Prosecuting counsel said that in June, 1943, Mrs. Warren applied for employment as an assistant to Dr. Lipkin, of Liverpool. She said she was an M.D. of Berlin University. Dr. Lipkin told her he could not employ her unless she was on the *Medical Register*. Mrs. Warren got a Miss Davies to sign a declaration that she had seen her certificate of qualification. The General Medical Council thereupon placed her on the Foreign List of the *Medical Register* as temporarily registered in pursuance of Orders made under Defence Regulation 32B. Dr. Lipkin employed her from November, 1943, to January, 1944. According to the report of the trial in the *Manchester Guardian* Mrs. Warren, when interviewed by the police in August last, said she had qualified by a correspondence course. She declined to go into the witness box. After the jury had returned a verdict of guilty Inspector Colshaw said she was a native of Liverpool. She had told a series of lies. One doctor had said she had not the slightest knowledge of medicine except stock prescriptions.

Mr. Justice Lynskey said he was satisfied that Mrs. Warren had never qualified to practise medicine. For her to treat people, pretending to be a doctor when she was not, might cause serious risk to the community. He sentenced her to six months' imprisonment.

R. G. Smith (*U.S. Nav. med. Bull.*, 1945, 44, 159) records his observations on 5 out of 40 men on board ship with mumps who developed orchitis, and all received 500 c.cm. of reactivated dried pooled plasma intravenously as an initial dose. The results were excellent and dramatic. One patient received a second 500 c.cm. of plasma when meningitic signs and symptoms appeared.

Reports of Societies

LATENT PERIOD BETWEEN ONSET AND RADIOGRAPHIC SIGNS

On May 18 Dr. James F. Brailsford read a paper to the Radiological Section of the Royal Society of Medicine on the significance of the latent period which elapses in most diseases between onset and radiographic signs.

He said that the radiographic signs did not coincide with the development of clinical signs, but lagged behind them, except in the case of the pulmonary metastases of sarcoma, which might have attained a large size before any clinical signs. The interval between the two manifestations varied not only in different diseases but in different lesions and sites of these diseases. The clinical signs might have disappeared before the radiographic signs appeared, and the latter might persist to the end of the life of a healthy individual. Obviously radiographs during the latent period would reveal no evidence of the disease, though it might be present. Further radiographs must be taken, after an interval depending on the condition, if they wished to obtain confirmatory radiographic evidence. The interval between the first negative radiograph and the request for the second which showed positive signs was usually very much longer than the latent radiographic period, probably because the first radiograph was of a patient with prominent symptoms which had shown some abatement in the interval, the second being only called for because of a recrudescence of symptoms or their failure to clear up within a reasonable time. The radiographic signs also lagged behind and might even seem to increase after the clinical signs had disappeared; hence it was necessary to wait to obtain radiographic evidence of the effect of any treatment. In pulmonary tuberculosis serial radiographs might show the progressive development of small lesions to complete destruction of most of the lungs even under the most favourable circumstances; while in other cases not only might the small initial foci vanish from sight but such spectacular appearances as those associated with miliary tuberculosis, consolidation, cavitation, and pleural effusion might entirely disappear under conservative home treatment. Therefore the severity of the past attack or attacks could not be judged from the residual radiographic appearance. From the latter it could not even be asserted that the disease was inactive, because a latent period followed reactivation; the significance of the radiographic findings could be appreciated only in the light of a previous clinical examination. Without such examination the interpretation of the negative or positive radiographic findings might be very erroneous. Progress in radiological interpretation would only come by helpful co-operation between clinician and radiologist.

The British Council for Rehabilitation held its first study course during the period May 7 to 11. The centres visited were Horton Emergency Hospital; Roffey Park Rehabilitation Centre; Queen Victoria Hospital Plastic Surgery Unit; the Government Training Centre, Slough; Queen Mary's Hospital Limb-fitting Centre; and Queen Elizabeth's Training College for the Disabled. The course began with a general survey by Dr. Harold Balme, and Mr. St. John Buxton, who followed, discussed the orthopaedic aspect of rehabilitation, and among other speakers during the week were Mr. John Hunter, Dr. T. M. Ling, W/O J. E. Blacksell on the work done for burned air-crew patients, Mr. Langdale Kelham, and Mr. E. S. Evans. The final session was devoted to a conference, over which Lord Rushcliffe, chairman of the council, presided, when Mr. Watson Smyth spoke from the point of view of the trainer of the disabled and Mr. S. J. Maude from that of the ultimate employer of those trained. After these opening addresses there was a general discussion.

J. H. Peters, L. Dexter, and S. Weiss (*Amer. Heart J.*, 1945, **29**, 143) record their observations on 56 cases of echinococcus infection of the left side of the heart by echinococcus cysts, to which they add five new cases. Although it is a rarity it represents a type of unusual heart disease for which surgical relief is promising now that improved technique and thoracic exploration have been developed.

Correspondence

Limits and Dangers of Blood Transfusion

Sir,—I was very much interested in the article written by Major-General W. H. Ogilvie (May 5, p. 619), but some of his statements on blood transfusion strike me as being open to criticism. General Ogilvie says: "To-day we know no limits, in amount or rate of administration, other than the needs of the patient." In my opinion there is a grave danger of overloading the circulation, even in an otherwise healthy adult. I know of one strong, healthy young man who was killed during the blitz by the rapid administration of six pints of blood. There was no reaction, but at post-mortem examination the right side of the heart was found to be full of blood to the point of bursting.

The other remark which I question is: "Fit men recently wounded can take any amount of O (IV) blood from a reliable blood bank." Does General Ogilvie consider it safe to give unlimited O (IV) Rh+ blood to an Rh− patient, especially without inquiring if the patient has had previous transfusions?

General Ogilvie is distressed about blood given during such straightforward operations as gastrectomy or resection of rectum. I can see no fundamental error in doing this, especially in the latter operation. Blood is given in these cases to combat shock and make convalescence smooth, and has little to do with loss of blood. The results in these operations have much improved since blood transfusions have been given, and the earlier the transfusions are given the better.—I am, etc.

Newport, Mon. J. T. Rice Edwards.

Surgical Lessons of War Applied to Civil Practice

Sir,—I have read with great interest Major-General W. H. Ogilvie's paper on surgical lessons of war applied to civil practice. Perhaps I may be allowed to underline the importance of one of the subjects he mentions—infrequent dressings.

In 1941 I was casualty surgical officer at a busy hospital in North London where we saw perhaps a hundred cases a day. There was a large, central, waiting hall with a skylight but no windows. There might be 50 or 60 people present on any busy morning, waiting on the benches or filing slowly into the M.O.'s room. It was the custom for dressings to be changed daily, and in order to speed up matters patients would often begin to take off their bandages as they advanced along the line; then a nurse with a jerk removed the last layer of gauze and the wound was ready for the doctor—and for contamination by the coughing crowd and the dust raised by children passing the time of waiting by running about. It was very difficult indeed to convince either the patients or the members of the nursing staff that it was not from laziness that I tried to restrict my inspection to temperature reading, palpation of regional lymph glands, and questions regarding severity of pain. Many a patient went away grumbling because he did not have his wound dressed; and the nurses murmured that there was "apparently no need for them any more."

Education will be necessary and the authority of the "honorary" will be needed to back up the junior surgeons in their attempt to alter long-established methods of the casualty department.—I am, etc.,

E. G. Herzog.

Varicose Veins: War Experience and Civilian Practice

Sir,—I read Major-General Ogilvie's article (May 5, p. 619) with great enjoyment and instruction. Anything he says carries authority to the whole of the English-speaking medical profession and is readily accepted by us, and particularly by the large number of Service surgeons whom he has so ably led, inspired, and instructed. In view of the weight of his opinion, there is one comment that he makes on varicose veins on which I should be glad of the opportunity to write—it is, that the "safest and most satisfactory way of destroying these calf varicosities without harming the deeper channels" is by "surgical extirpation."

In my experience most of these veins can be cured by ligature and injection of the long saphenous vein at the internal malleolus, after the complete Trendelenburg operation (as General Ogilvie details) plus simultaneous injection of 20 c.cm. of 30% saline at both places. Hypertonic saline is an effective and permanent sclerosing agent for varicose veins when used in this way. In addition it is safe, because if some of it does leak into the main circulation it is rapidly diluted to saline and will not damage healthy endothelium. Doses of 20 to 40 c.cm. of 30% saline have been injected into the veins of the arm in my practice since 1923 for the relief of cerebral and post-spinal headaches and restoring the fall in blood pressure that takes place with a spinal anaesthetic.

In a few patients the leg varices will not be effectively sclerosed by ligature of the long saphenous vein at the groin and ankle. Some of them require ligature of one or two communicating veins in the lower third of the internal surface of the leg in addition. These are detected by palpation with the tips of the fingers, for at the point where they emerge through the deep fascia it feels as if there is a hole in the leg. The back pressure in them is high and no sclerosing agent is effective for long. Last, a few people have incompetence of the short saphenous vein, and this must be tied and injected in the popliteal space. I would emphasize, however, that only a small proportion of patients need this treatment of ligature and injection of the communicating veins and short saphenous vein.

It would be a tragedy if surgeons started to treat varicose veins in the leg by surgical excision, for there is a simple and safe cure which has been perfected through the years of the war and tried out on civilian patients over the whole range of working-life, beginning with men and women on war work in their late 'teens to those in their seventies still working. Excising clusters of veins from the legs, apart from being unnecessary and possibly not curative, will be certain to be followed by sepsis and unnecessary incapacitation. It is often an oedematous, eczematous, and ulcerated field, in fact a pest-ridden swamp, and the less surgery here the better.—I am, etc.,

London, W.1. HAROLD DODD.

Carbachol and its Antidote

SIR,—I do not think there is any need to qualify the statement that atropine is an effective antidote for carbachol as Dr. Hugh Dunlop suggests (May 19, p. 710). Atropine antagonizes the action of all choline esters on the heart, the blood vessels, the intestines, the bronchioles, and the central nervous system fully, and does so just as well after the choline ester is given as before. The abolition of the effect of large doses of carbachol by atropine is regularly observed by students in their practical work here. Of course if the injection of atropine is delayed until carbachol, by filling the bronchioles with mucus, has brought the patient to the point of death, his life will not be saved. Dr. Dunlop makes the remarkable statement that: "When, by mistake, the dose of carbachol given is of the order of two hundred times the therapeutic amount the patient exhibits often a phase of severe hypertension." On how many patients, given such a dose, has Dr. Dunlop made this observation? How "often" has he seen such patients? It is true that atropine will not paralyse the action of carbachol on sympathetic ganglia or on the suprarenal medulla, and therefore it is likely that when atropine is used as an antidote for a large dose of carbachol there will be a large rise of blood pressure due to an intense stimulation of the sympathetic system. But this will not kill the patient or do him any permanent harm. It is surprising how little a cat or a dog is affected by a single intravenous injection of a large dose of adrenaline; there may be temporary collapse, but the animal survives.

As for Dr. Dunlop's opinion that the two "mishaps" from carbachol would probably not have been averted by the use of atropine, from my experience with animals I would say it is as safe a prediction as can be made that a patient who has had a large overdose of carbachol can be saved by atropine sulphate. In such an emergency it would be wise to give it intravenously, and to repeat the injection if necessary.—I am, etc.,

Department of Pharmacology, Oxford. J. H. BURN.

Sulphonamides and Measles

SIR,—Dr. L. Sheldon (May 12, p. 680) writes: "The dosage for children of 1 to 6 years was 1/4 tablet four-hourly." On the same page R. J. Eadie writes: "It is rightly recommended in acute infections that where sulphonamide chemotherapy is used it should be administered in full doses, and that the blood concentration should be kept at an efficient bacteriostatic level for the duration of the course, which is limited usually to 7 or 8 days." Surely a dose of 1/4 tablet—a tablet presumably of 0.5 g.—is quite inadequate in an acute infection like measles.

Incidentally, regarding toxicity, I have a letter from the home doctor of a boy who has just come to this school. He says: "I thought it as well to let you know that he is intolerant of sulphonamides in any form and liable to become convulsed and unconscious after quite small doses." I have never seen unconsciousness and convulsions following their administration nor can I recollect having seen them recorded. It would be interesting to know the frequency of these alarming conditions. —I am, etc.,

A. S. HENDRIE,
Gresham's School, Holt. Medical Officer.

SIR,—Reading the enthusiastic reports on sulphonamide treatment of measles, which seem to advocate the routine treatment of all measles cases with one of the sulpha drugs, I feel prompted to record my experiences in 152 cases, seen during the last five years, since I have been using sulphathiazole, sulphadiazine, or sulphamezathine. No case, however serious, was sent to hospital, and none of my patients died. This does not mean much, as the mortality generally has declined to what appears in the last epidemic as under 0.05%. All patients, irrespective of treatment, and with the exception of a few cases of bronchitis and one of bronchopneumonia, were well and up again within a week after the eruption of the rash. In 63 cases reliable temperature charts were kept until five days after the rash appeared. In the great majority of cases thus observed, and probably with all my patients, the temperature dropped to below 100° F. 36 hours after the rash had fully developed, and it remained low without any treatment. It did not matter if the patient looked seriously ill in the prodromal stage or stage of eruption; they were all comfortable 48 hours later.

I have treated only 26 cases of complications, or anticipated complications, with sulphonamides. I was prepared for complications if the temperature remained above 101° F. 36 hours after the rash was fully out. The complications included 6 cases of otitis media, one of which developed otorrhoea during the sulphonamide treatment; 3 cases of capillary bronchitis; 2 cases of bronchopneumonia, one of which developed during the sulphamezathine treatment (probably the initial dose was insufficient); and one of confluent bronchopneumonia in a baby of 15 months, whom I saw for the first time four days after the measles rash. All responded well to massive doses of sulpha drugs, and, with one exception, were well and without pyrexia after 36 hours. Especially gratifying and surprising were the three cases of capillary bronchitis, which all occurred within 48 hours after the rash. The patients were cyanotic, with respirations up to 60, and the ominous pale rash. Contrary to expectation, this condition, which is believed to be caused by the measles virus itself, responded promptly to massive doses of sulphadiazine. Bronchitis in children who had a history of bronchitis, asthma, or whooping-cough in the previous year was not improved by the treatment. I examined practically every case during the eruption stage with the auriscope, and I found a red ear drum in about 25%. Though some of these patients complained of an occasional earache I did not consider it an indication for treatment with sulphonamides. None of these cases developed otitis media. I gave sulphadiazine prophylactically to eight children who had been in close contact with measles, starting five days before I expected the rash to develop. Prodromal symptoms and the rash seemed to be uninfluenced.

There is, in my opinion, no justification for routine treatment of measles cases with the sulpha drugs at present, and under home treatment. Hospital experience may be different, though Joyce Wright, in the *Journal* of March 3 (p. 285), seems to come to the same conclusion. Complications are few and can generally be kept under control with the sulphonamides when they arise. The stage of " illness " after full development of the rash appears to be too short to warrant treatment with a possibly toxic drug. If sulpha drugs were given on such a large scale undesirable toxic incidents would have to be expected more often.—I am, etc.,

London, W.9. F. Muller.

Nursing of Measles Patients in Hospital

Sir,—With recommendation (*a*) of Dr. Joyce Wright's paper on ear disease in measles (March 3, p. 288) everyone should agree. A minimum of 12 feet between bed centres should be the rule in every ward in which infections of the upper respiratory tract form a part of the work. To this we may add that no bed centre should be nearer to the end wall than 6 feet. These two points, with sufficient space between the ends of the beds, may be said to make up the internal ventilation of a ward. There must also be free external ventilation. This warning is necessary because of the crowding that has gone on in nearly all our hospitals as a result of the war and the building of blast protection outside the windows. Because they have had no deadly infections spreading through such wards physicians, surgeons, and administrators without special experience have weakened on the importance of these things. A generation of students and nurses has gone out into the world brought up under these cramped conditions; and examples can easily be found of how those working in a hospital can become mentally immune to the insanitary conditions they have always been used to and take for granted. Dr. Wright's warning is salutary, and all the more so as she writes from one of the fever hospitals taken over from the old M.A.B. which have had practically the only wards in London run under proper hygienic conditions during the past five years.

With recommendation (*b*) we may also agree, not so much because of infection of the middle-ear cleft, which at this age is not dangerous and should be recoverable, but because of its devastating effect on the alimentary tract under 1 year of age. It is when we come to recommendation (*c*) that I begin to cross swords with her. As to (*d*), I have not worked in a ward submitted to the modern control of dust-borne infection, but I am sure it is necessary. With nearly the whole of recommendation (*e*) I disagree, except in so far as it describes the general principles of nursing carried out by every careful mother. Of recommendation (*f*) one would not complain, but I am in absolute opposition to recommendation (*g*), which I have known to do inestimable harm, and recommendation (*h*) is another subject.

The paper is an example of that pseudo-scientific type of medicine that is becoming so fashionable to-day, which looks only at the invisible invading organism and does not see the human being lying in the cot. It is a convincing piece of evidence in favour of that treatment of the child as a physiological unit which was developed in the 'twenties by many M.O.s of the M.A.B. when I was the first visiting consultant. It is regrettable that the misuse of isolation wards and the discovery of types of streptococci have prevented that treatment from being carried out with the same enthusiasm as it was in 1930, and I doubt whether the results of otitis media in acute infectious diseases are as good as they then were. It is, however, still carried out in its entirety at the Grove Hospital. Dr. McEntee has sent me his figures for the same period as that of Dr. Wright's paper—429 cases, of which 21 developed otitis media after the fifth day, an incidence of 4.9%. Not that statistics mean anything in these cases, except for one figure, and that is the number that are not well with a dry ear and normal hearing at the end of eight weeks from the day of discharge. At the Grove there was one doubtful case. Dr. Wright does not refer to this dominating date in otology, but she mentions another figure which is illuminating—18 mastoid operations were performed in 496 patients: at the Grove none. Leaving out those done for gastro-enteritis—a condition that was held to be an indication for a mastoid operation at that time—too many mastoids were being done either because of a fallacious plan of campaign or because of the timid interpretation of the indications for mastoidectomy. I suspect the former, though the six operations done in children under 2 are regrettable, for at this age the operation is seldom necessary.

The child as a physiological unit connotes three things that are germane to the subject. The erect position which admits of Eustachian drainage, movements of the muscles of the pharynx which stimulate this drainage, and activity which increases the circulation. This is the only way in which any influence can be exerted on the mucous membrane of the middle-ear cleft. The " ear treatment " is simply a toilet of the meatus. Treat the child and he will get well. When a roar of welcome greets the doctor or a nurse on their entry to the ward ears dry up; when all is " prunes and prisms," or the children under 2 are allowed only the exercise of their cots they will not.

We know that by the time the children are well enough to run about no harm comes from throwing them all together whatever the haemolytic streptococcus concerned. We learnt that at the special ear clinic at the Southern Hospital, which is still an integral part of the organization for the treatment of otitis media in the fever service of the L.C.C., though it had temporarily to be shut down when preparations were begun for the E.M.S. We saw it at Joyce Green, where Dr. Mitman provided a ward for all the ear cases after the 21st day of discharge, during which he had them all isolated in the bed next to the doors of the ward. This was a reasonable compromise between the two schools. Every one of those cases got well and not one operation was performed. I know how harmful is " the procedure followed in bed-isolation wards," where the child is " restricted to his own bed area " and not allowed to associate with his little friends, because ears will not get well with that limited activity, and they hang on until the middle-ear cleft becomes infected by the skin organisms and chronicity results with its otitic morbidity and life-time risk of otitis mortality.

And now for recommendations (*e*) and (*h*). I doubt whether the modern nursing habit of pushing things into a baby's nose is good; certainly they should go no further than the inturned area of skin where " bogies " form. " Discard jars " should not be used; the scientific anti-cross-infection receiver is a small paper bag into which the pledgets and sticks are thrown, the mouth of the bag is then screwed up, and the whole thrown into the flames. These streptococci can only have touched the thumb and two fingers of each hand. Of course a nurse should wash her hands. Sterile wool is unnecessary; it is also harmful because the sterilization breaks up the fibres and the wool adheres less well to the sticks so that the mops are more likely to be left in the meatus. Of course bedpans should be cleaned, but these contain the organisms of the alimentary canal, not of the upper respiratory tract. Even in typhoid the organism in the ear is a haemolytic streptococcus. As to mugs, spoons, and forks being boiled, I agree as hospital equipment develops; but no one has come to any harm from them when they have been properly washed. The " no-touch " technique is not suitable for a mastoid wound. I have seen cases go wrong from a slavish adherence to a stereotyped technique. It is the patient's skin that matters, not the dresser's. Keep it dry and don't let skin touch skin where pinna and scalp meet. You cannot do that efficiently with two pairs of forceps. The child with his bed covered with toys and books is always a difficult one, but to deprive them of all toys and books is unkind. As one of my correspondents on this matter says: " You cannot put morale into a statistical table."

Barrier nursing I have already dealt with. There remains the question of sulphonamides. I think that every case of otitis media with discharge should be given a course of sulphonamide therapy. Not that it cures the otitis media, but it stops invasion in some cases where otherwise it would occur. But the nurse should not keep the patient from the upright position and activity longer than is essential. I do not agree with " claymore therapeutics," where time and time again the microbe is given hard hits that lay the patient low. In two cases it was suggested that an operation must be necessary because the drug did not cure the condition. The sister of the ward got the patient well in a few days by the method of physiological activity that she had learnt in the special ear clinic at the Southern Hospital.—I am, etc.,

T. B. Layton,
Palermo. Otologist to the London Fever Service, 1920-44.

Desert Treatment of Chronic Otorrhoea

SIR,—To the recent correspondence on the treatment of chronic otorrhoea might I submit another line of treatment. The high incidence of inflammatory and suppurative diseases of the ear, primary and recurrent, in the Middle East tempted me to try a completely new line of treatment, and the initial results have been almost dramatic. All the cases were treated at a field hospital in the desert under adverse conditions. The outline of treatment is as follows:

1. Auriscopic examination and the condition noted.
2. Irrigation of pus, debris, and wax in all types of cases, and whenever these are found, with solution of sodium bicarbonate 1 drachm to 1 pint of warm water.
3. The patient holds the auricle upwards, outwards, and backwards by extending his hand across the vertex in the usual way.
4. Hot air is blown into the meatus three times a day through an aural speculum by means of a Eustachian catheter heated over a spirit lamp, and pumping is supplied by a Politzer bag. Initially a dental hot-air syringe was used.
5. The air feels "cold" to the patient after 20 pumps of the bag on an average, and the patient is instructed to say "cold" when the air ceases to be warm.
6. I have employed 7×20 pumps three times a day, the whole procedure, including heating, taking from 3 to 5 minutes.
7. In cases with copious discharge and resistant to treatment hot air was also blown through the Eustachian tube via a catheter, but frequently in cases with large perforations of the drum the air when blown into the ear was felt by the patient to enter the nose.
8. Light plugs of wool inserted in the ear after each treatment.
9. It is advisable for the operator to wear a mask.

The chief points of interest found in the treatment were: (1) The majority of the patients took a keen interest in the treatment. (2) The rapid disappearance of pain in acute cases. Often the patients would come and ask for a treatment if pain recurred. (3) Favourable response in very chronic cases. (4) No medicaments are used; therefore the treatment is economical. (5) By means of a bath thermometer the estimated temperature (dry heat) obtained is roughly 200° F. (6) Many of the chronic patients remarked on the rapid disappearance of discharge and pain with this treatment as compared with previous treatments. (7) In several cases recent perforations actually disappeared. (8) The cases were not chosen ones, and where two ears were affected the more severe was treated by this method and the other with sulphonamide in glycerin (5%), and in these cases the hot-air treatment gave better results. (9) In no single case was there complaint of burning sensation during treatment. (10) Patients can easily be trained to carry out the hot-air part of the treatment on one another, and this was actually the practice in my department.—I am, etc.,

C. J. SCOTT,
Kent Aural and Ophthalmic Hospital, Maidstone. Major, R.A.M.C.

War Neuroses after Psychological Trauma

SIR,—Air Commodore Gillespie's description of Freud's account of the traumatic neuroses (May 12, p. 653) cannot be allowed to pass without correction. In the first paragraph dealing with this subject he quotes from Freud's *Beyond the Pleasure Principle* (published 1920, translated 1922): "I think one may venture, tentatively, to regard the ordinary traumatic neurosis as the result of an extensive rupture of the barrier against stimuli." At this point the quotation marks are closed but he continues to quote verbatim: "In this way the old [naive] doctrine of 'shock' would come into its own again, apparently in opposition to a later and psychologically more pretentious view, which ascribes aetiological significance not to the effect of the mechanical force but to the fright and the menace to life." Here his quotation ends, but Freud goes on to say, "but these opposing views are not irreconcilable, and the psychoanalytic conception of the traumatic neurosis is far from being identical with the crudest form of the 'shock' theory." I can only quote Freud unabridged as it is so condensed. Air Commodore Gillespie's quotation of odd sentences from it, which comprises the next part of his paragraph, has changed the original meaning.

> "While the latter [shock theory] takes the essential nature of the shock as residing in the direct injury to the molecular structure, or even to the histological structure, of the nervous elements, we seek to understand the effect of the shock by considering the breaking through of the barrier with which the psychic organ is provided against stimuli. and from the tasks with which this is thereby faced. Fright retains its meaning for us too. What conditions it is the failure of the mechanism of apprehension to make the proper preparation including the overcharging of the systems first receiving the stimulus. In consequence of this lower degree of charging these systems are hardly in a position to bind the oncoming masses of excitation, and the consequences of the breaking through of the protective barrier appear all the more easily. We thus find that the apprehensive preparation together with the overcharging of the receptive systems represents the last line of defence against stimuli. For a great number of traumata the difference between the unprepared systems and those prepared by overcharging may turn the scale as to the outcome: with a trauma beyond a certain strength such a difference may no longer be of any importance. When the dreams of patients suffering from traumatic neuroses so regularly take them back to the situation of the disaster they do not thereby, it is true, serve the purpose of wish fulfilment, the hallucinatory conjuring up of which has, under the domination of the pleasure principle, become the function of dreams. But we may assume that they thereby subserve another purpose, which must be fulfilled before the pleasure principle can begin its sway. These dreams are attempts at restoring control of the stimuli by developing apprehension, the pretermission of which caused the traumatic neurosis. They thus afford us an insight into a function of the psychic apparatus, which without contradicting the pleasure principle is nevertheless independent of it, and appears to be of earlier origin than the aim of attaining pleasure and avoiding pain."

Any question of paradox, "the greater the apprehension the less the likelihood of developing a traumatic neurosis," as suggested by Air Commodore Gillespie, is dispelled by this full quotation.

In the next paragraph headed "Simple Traumatic Neurosis" Air Commodore Gillespie states: "The central feature of the classical traumatic neurosis has been the recurrent dreams which recapitulate the traumatic event. Freud (1922) made it the point of departure for his observations on the repetition-compulsion phenomena." Continuing to quote from Freud where I left off: "This is therefore the moment to concede for the *first* time an exception to the principle that the dream is a wish fulfilment . . . they obey rather the repetition compulsion, which in analysis, it is true, is supported by the (not unconscious) wish to conjure up again what has been forgotten and repressed. Thus the function of the dream, viz., to do away with the motives leading to interruption of sleep by presenting wish fulfilments of the disturbing excitation, would not be its original one; the dream could secure control of this function only after the whole psychic life had accepted the domination of the pleasure principle." So the dream by its development of apprehension can be regarded as a method of repetition compulsion to deal with the intruding stimuli. Freud discusses repetition compulsion in a paper (1919): "We are able to postulate the principle of a repetition compulsion in the unconscious mind, based upon instinctual activity and probably inherent in the very nature of the instincts—a principle powerful enough to overrule the pleasure principle, lending to certain aspects of the mind their daemonic character and still very clearly expressed in the tendencies of small children." In *Beyond the Pleasure Principle* he further elaborates his views on the subject, and demonstrates the part it plays in mastering painful experiences. Then he modifies his views on the dream as a wish fulfilment to bring them into line with this new discovery. (*Vide* quotation above.) Air Commodore Gillespie then continues: "It would not invalidate his [Freud's] speculation on repetition if this kind of dream were to be found to depend not on disturbance of the organization of the ego but on more primitive properties." As I have just shown Freud does consider repetition compulsion to belong to that borderland between physiology and psychology—i.e., the instincts. With regard to the traumatic dream itself, its outstanding characteristic is its exact photographic-like reproduction of the actual happening and is in no way whatsoever the result of any ego elaboration; this in itself places the dream in a different category to those of the pleasure principle, which are essentially ego elaborations, and, as Freud has shown (in my quotation above), are the result of disturbances in the ego. Air Commodore Gillespie goes on to say, "This type of dream may be regarded *instead* [italics mine] as a preservative phenomenon at the physiological level." If instincts belong to physiology then this is exactly the argument which Freud advanced in *Beyond the Pleasure Principle*, and is generally accepted as a true statement by psychoanalysts.—I am, etc.,

Bishop's Stortford. D. N. HARDCASTLE.

Ovariotomy or Caesarean Section?

Sir,—I desire to express my gratitude for the sage and humane counsel of Mr. Victor Bonney (March 31, p. 459) and for Prof. S. J. Cameron's example (March 3, p. 307) of how to section a patient in bed when circumstances demand it.

Mr. McIntosh Marshall (March 24, p. 421) is one of the pioneer exponents of local analgesia for Caesarean section. My regret is that I did not follow his lead sooner. Local analgesia is undoubtedly ideal. The relaxation of the abdominal wall permits one to discard retractors. The uterus contracts and retracts so beautifully that I am persuaded the blood loss is less than for normal delivery. I find that I have barely time to clear the mucus from the throat of the infant, which is usually born with its eyes wide open, and lay it between the legs of the mother before the placenta presents itself in the wound. Child and placenta together are handed to the nurse with instructions not to sever the cord until pulsations cease. This may be accomplished, using 1 in 2,000 nupercaine solution, by bilaterally blocking thoracic nerves 8, 9, 10, 11, and 12 each with 7 to 10 c.cm. anaesthetic solution and infiltrating 10 c.cm. around each iliohypogastric nerve in its course through the internal oblique muscle from 3 to 4 cm. above to 2 cm. medial to the anterior superior iliac spine. When the abdominal cavity is open 5 c.cm. of the solution is infiltrated on each side of the bladder into the extraperitoneal tissue and 10 c.cm. beneath the peritoneum in the vesico-uterine excavation. To prevent the parturient being distressed by the theatre display, needle pricks, etc., she is given a subcutaneous injection of 15 mg. omnopon or morphine before the operation (2½ hours for preference, if time permits), and on the table she is kept from moving her limbs by the very lightest chloroform or vinesthene narcosis. Before she leaves the table the mother is shown her baby, and on her return to the ward she is given a cup of tea or ovaltine as she prefers, turned into Sims's posture, and so to sleep.

Post-operative nausea and headache are abolished and the improved well-being of the mother is very evident. Nupercaine is boilable and does not inhibit the action of the sulpha drugs—an important matter when operating on a patient whose membranes may have been ruptured for 24 hours, and who may have been examined repeatedly by unclean native midwives before admission to hospital. I would never revert to other types of anaesthesia except at the express desire of a patient or where a suitable local analgesic agent is unobtainable.—I am, etc.,

Poona. F. R. W. Kinkead Allen.

Women in Labour

Sir,—I have read the correspondence of Dr. Elam and others in your recent issues with great interest. It is yet another incident in the "ever-since-Simpson" controversy upon anaesthesia and labour. Dr. Violet Russell mentioned my name in her contribution on April 28, and I am constrained to comment, apologetically, as my remarks may be considered to be irrelevant and her reference to my work misunderstood.

It appears that the general consensus is that an anaesthetic must be given in labour or woman suffers unbearable pain. The assumption that normal labour is painful is erroneous. Surely painful labour is abnormal, or must we admit that the human race in order to survive is subjected to pathological adventure? Do scientific and biologically minded men, even though they may have no particular philosophy, really accept without question that the most desirable experiences of a woman's life, and her obvious natural urges, are rewarded in their ultimate perfection by an ordeal of pain and danger?

It remains a fact, however, that labour is painful in the large majority of cases, particularly those attended by members of the medical profession. In the absence of primary physical abnormality, painful labours are due to abnormal emotional states. The pain–fear–tension syndrome and its physical manifestations cannot be fully discussed here, but I seriously urge obstetricians to inquire into this matter. The factors concerned with interpretation and intensification of sensory stimuli are important, because the mechanism of dilatation and expulsion depends upon them for their integrity.

The emotional states of a woman in labour have variations within normal limits without disturbing neuromuscular harmony or polarity. They are constant and amenable to care and treatment. Controlled emotional influences dispense with both the desire and the desirability for anaesthesia. Natural childbirth is not only free from unbearable discomfort, but attended by a pleasing and satisfying sense of accomplishment—a reward of which many women do not wish to be robbed by enforced unconsciousness. There are hundreds—probably thousands—of women in this country who can testify to the truth of this statement, but they remain silent because they are happy in their own experience, and have no desire to be called lunatics or liars by acquaintances who have themselves been allowed to suffer.

As I have written elsewhere: "It must be recognized that if and when emotional manifestations are abnormal parturition becomes pathological, and requires treatment by scientific means as expeditiously as an obstructed labour. It is a serious complication, and one of the major causes of maternal morbidity."

Anaesthetic must always be available and ready for use. We all should use it when pain threatens, but once natural painless labour has been witnessed without prejudice, anaesthesia becomes an emergency or adjuvant, instead of an adopted routine, for pain is recognized and treated as an abnormality. The difficulties that have strewn the path of this teaching are almost unbelievable when such a prize is at stake as the abolition of the fear of childbirth. But we are a conservative profession, and demand numbers, statistics, and controls before accepting innovations contrary to orthodoxy.

Students have only recently been instructed in the emotional influences of pregnancy, and their curriculum must conform to the requirements of examiners. I recently had the privilege of visiting a number of the universities in the British Isles, and found that, with few exceptions, the organizations and structure of the maternity teaching hospitals make educational changes difficult, and until these obstacles can be overcome we must expect painful labour and the general use of anaesthetics.—I am, etc.,

Woking. Grantly Dick Read.

Sir,—I have read the letter by Mr. John Hamilton (May 19, p. 714) with interest. The psychological aspects of childbirth and its related processes, such as lactation, have been largely ignored and the average labour is by no means necessarily a normal one. I agree with Mr. Hamilton's recommendation that the suggestive word "pain" would be better replaced by the innocuous term "contraction." Furthermore, the relieving of muscular tensions would help to attain "a calm conduct of the ante-natal period" and of the labour itself. This subject has been described in detail by Jacobson (*Progressive Relaxation* 1938) and has been used in pregnancy and parturition by Grantly Dick Read (*Revelation of Childbirth*, 1942). I woul add that this method has also been found useful in hypertension and for sleeplessness, and might have been mentione with advantage in the reply to the question on insomnia (p. 721).

Too little attention is paid to the psychological aspects o general anaesthesia also. I have known hospital sisters t enter the theatre with a cry of "Nurse! You've forgotten t bring the vomit bowl," while I have been attempting a peacefu induction.—I am, etc.,

Sheffield. R. O'Rahilly.

Infant Deaths

Sir,—The letter of Dr. T. B. Sellors (April 28, p. 607) contains the fantastic suggestion that "swaddling" is necessary i order to restrict a baby's natural movements "to ensure re which is one of the essential needs of early animal life." Wh should the human infant be subjected to such maltreatment Newly born lambs and other very young animals are burstin with energy and require no swaddling or binding to restri their healthy and vigorous movements. Nature makes pr vision for some freedom of movement before birth by floatin the child in liquor amnii. Abdominal paracentesis of the pre nant uterus has been shown to be practical for certain radi logical investigations, so why not interfere still further wi Nature and perform a paracentesis regularly during pregnan and drain off liquor so that the uterine muscle can caress ar "swaddle" and inhibit the movements of the growing bab

Dr. Sellors's reference to swaddling as "a universal custom from time immemorial" set me searching for references in many obstetric textbooks and books on paediatrics both British and American, but with no success. That massive work on *Woman* by Ploss and Bartel made no reference to the care of the baby. I had no success with the *Encyclopaedia Britannica*, but the *New-Born Baby* by Dr. Eric Pritchard proved of great interest and gave quotations well worthy of repetition.

Dr. Pritchard refers to infants' clothing which "fulfils the necessary conditions of comfort, warmth, economy, cleanliness, facility for free movement, and skin activities." There is a delightful chapter on nursery fallacies. He says: "Many of the most egregious nursery practices find their sanction in antiquity, and owe their perpetuation to the conservative adhesion to authority which is shown by even the greatest of the masters of medicine . . . who, each in turn, followed blindly in the footsteps of his predecessors." He quotes from Dr. George Still's work on the *History of Paediatrics*, which I have not seen:

> "First as regards binders. These monstrous inventions, which in modified and mitigated form have survived until the present day, originated in the dark periods of medicine when 'swaddling' along with 'salting' was regarded as an essential part of the hygienic ritual of the newborn (Galen, A.D. 130)." In 1472 Paolo Bagellardo "gave full details of the method of binding up the arms, body, and legs of newborn babies, so that the child might be properly shaped . . . to the end that the baby should not become a hunchback, but be properly pressed into shape." He quotes Mauriceau (1668): "Let his [the baby's] Arms and Legs be wrapped in his bed and stretched strait and swathed to keep them so, viz., his Arms along his sides and his Legs equally both together with a little of the bed between them that so they may not be galled by ubbing one another: after all this the Head must be kept steady and strait with a stay fastned on each side the Blancket, and then wrap the Child up in Mantles or Blanckets to keep it warm. He must be thus swaddled to give his little body a strait Figure, which s most decent and convenient for a Man and to accustom him to keep upon the Feet, for else he would go upon all four as most other Animals do." Again he quotes the English physician, William Cadogan, who wrote in 1748: "The first great mistake is that they think a newborn infant cannot be kept too warm: from this Prejudice they load it and bind in with Flannels, Wrappers, Swathes, tays, etc., commonly called Cloaths, which altogether are almost equal to its own Weight." John Cooke, another Englishman, wrote n 1769; "If they were not swathed, but allowed as much freedom s puppies, it would be much better for them, as I have shown in ormer discourses on the cause of the surprising mortality of infants under two years of age." Dr. Pritchard finishes this section with he comment: "Binders, long clothing, tight shawls and other impediments to free movement, by hampering muscular action, delay the eneral development of the body as a whole, encourage weak backs, pinal curvatures, and pot belly, and by restricting the expansion of he abdomen predispose to inguinal hernias."

No doubt the Association of Maternity and Child Welfare entres has done much to rationalize clothing for the newborn baby, but all this can be of little benefit if a final firm lanket is securely wrapped and fixed to immobilize the hapless fant. In my experience it usually is a firm blanket and not loosely knitted shawl lightly applied. No one suggests that e object of this tight wrapping is to deform the child, as in roducing the tiny foot of a Chinese lady or the distorted skull the Incas; the reason, I am told, is to prevent thumb-sucking. hat a penalty!

Before writing my original letter (April 14, p. 529) I made rtain inquiries which lead me to believe that tight wrapping as "widespread" and not merely a local atrocity which had me under my notice. Dr. Sellors's letter is mostly irrelevant d he endeavours to side-track the issue, but I am more than er impressed with the extreme importance of this matter. veral national and provincial papers printed extracts under ch headings as "Babies Tucked up too Tightly," and although is publicity has not improved the cordiality of certain memers of the nursing profession toward me I believe some little od has been achieved. John Cooke's observation quoted ove is worthy of special note.

I hope paediatricians whose status will command respect will ake some definite pronouncement if their experience is similar mine, and that many doctors who are competent to judge l play their part in investigating my "mischievous belief" d helping to prevent further waste of life.—I am, etc.,

Huddersfield. S. H. WADDY.

Bread and the Bowels

SIR,—The *Journal* of March 17 has just reached me and I was interested to read the report of the Nutrition Society on bread (p. 379). For the past five years my family and I have been stationed in the centre of India at a railway junction. Owing to the absence or high price of imported (and transported) goods, we have been compelled to eat those foods which are grown in the district. The grain, vegetables, pulses, fruit, etc., mostly come to us from within a radius of 50 miles or so. The basic diet of the district is wheat, dal (lentils), spinach, to which for the more wealthy may be added milk, butter-fat, and rice.

It has been our custom to buy a bag of wheat at harvest-time, and from this during the ensuing year quantities are taken as required and ground in the local "punchukki." The flour so obtained is made into leavened wholemeal bread or into chuppatties. A special hard wheat is also used to make a very palatable porridge. The flour obtained from the "punchukki" is 100% extraction, and from this the cook picks out the coarser particles but no more. This high-extraction wheat flour, then, has been the basic diet for us and our children for the past 5 years, and we consider that it has been on the whole very beneficial. Its most obvious and rapid effect has been on the bowels: two normal movements a day (except perhaps in the hottest weather) have been the rule as with the healthy Indians around us (an Indian who gets only one movement a day usually considers himself to be rather constipated).

For those liable to diarrhoea (convalescence after dysentery) and perhaps in some children under 2 years this high-extraction flour may be too coarse. For a healthy adult I would suggest that the best form of wheat for the table was a well-made fresh chuppatty with butter—better than white bread for the general health, perhaps better than leavened bread for the teeth, and having with butter a pleasant enough taste to make jam unnecessary. However, Britain will never adopt chuppatties, and in any case the "double roti" saves the housewife considerable trouble and time.

The first important point I would like to make is that I believe (correct me if I am wrong) that in these coarse diet, wheat-eating areas of India duodenal and gastric ulcer, appendicitis, etc., are fairly uncommon (in spite of the chillies). I think you would find cancer of the stomach also low, but as I have no statistics before me I will not press the point. The second point is that I believe if given the choice the vast majority of the British people would choose white bread to brown; they certainly would have done pre-war. As a vehicle for jam white bread is very pleasant. The third point is that unless bacon and eggs are as good for the bowels as high-extraction wheat flour what is lost upon the roundabouts by milling is not gained upon the swings by eating eggs and bacon. The fourth point is that with the coming of peace, and the availability again of large amounts of jam, chocolate, lollypops, and other kinds of sweets, wholemeal bread will be more, not less, necessary for the health of the population.—I am, etc.,

Itarsi, C.P., India. M. L.

"Bread—Defeat and Victory"

SIR,—Sir Ernest Graham-Little (May 26, p. 750) writes, ". . . it may profitably be noted that Russian soldiers have won their resounding victories on a diet mainly composed of whole-grain bread." Our gallant ally Soviet Russia first retreated then advanced on whole-grain bread. Our enemy Germany, on the same bread, as a corollary, first advanced then retreated. With such perfectly controlled experiments, it is difficult to see why Sir Ernest should consider there is a causal relationship between "intake of bran" and "output of victories."—I am, etc.,

London, W.1. J. DOUGLAS ROBERTSON.

Chlorine Inhalation for the Common Cold

SIR,—Some years ago I was impressed by two patients who accidentally inhaled chlorine while suffering from colds, and whose colds promptly recovered. I found that I could invariably abort my own colds by inhaling small quantities of chlorine gas, and, in fact, have not had a cold since I adopted this method two years ago. But I was doubtful if the mucous membrane would stand the insult. However, after being re-

reassured by an eminent laryngologist that ciliated epithelium could regenerate in four days, I decided to try chlorine as a cold cure among the workers in a small factory engaged on important war work, where absenteeism from colds interfered with production.

The method adopted has been to add 30 minims of HCl fort. to about 2 drachms of pot. chlorate in a dry 8-oz. bottle, allow to stand stoppered for 15 minutes, and add water gradually to dissolve the chlorine. The victim is persuaded to attend the first-aid room once an hour, when the unstoppered bottle is held under his nose, and he must sniff sufficiently hard to make him cough. On the first occasion he is given 5 grains of aspirin and a tablet of benzedrine to clear his head.

All those who volunteered to be treated in this way were sufficiently relieved to continue the treatment with enthusiasm. None took longer than three days to cure; most took one or, at most, two days. In January, February, and March this year 62 people with colds were so treated, and between them lost only one day's work. The sceptics, who did not attend, in some cases stayed at work with their colds, but 13 people stayed away, sending medical certificates that they had colds, and between them they lost 44 days of work. The total population at risk averaged 225. I have had no complications, such as sinus infection or bronchitis, in any of the treated cases.—I am, etc.,

Ashtead. W. Edwards.

Sulphonamides in Pus

Sir,—It seems to be a generally accepted clinical rule that sulphonamides are inactive in the presence of pus. (Local treatment [of otitis media] by sulphonamides is irrational because . . . the drug . . . is inactivated by pus (*Journal*, April 29, p. 617). In October, 1944, we were anxious to obtain a culture of the gonococcus to make antigen for the complement-fixation test. We chose—for culture on citrated rabbit's blood agar—urethral pus containing many gonococci, demonstrable by Gram-stained smears, showing a minimum of contaminating bacteria, and taken from recently infected persons on their first diagnostic visit. All our cultures were negative. We made a number of attempts, using media in triplicate, but to no effect. In spite of the well-known difficulty of growing gonococci these results were so different from our previous experience that we made inquiries as to the nature of any treatment undergone by the patients before we had seen them. We found that they had all been taking sulphathiazole—6 g. a day for twenty-four hours—before attending the laboratory. After learning this we treated our media with procaine (novocain)—para-aminobenzoic acid being unobtainable—and then found that our media supported the growth of gonococci, even though the patients continued as before with their sulphonamides.

It is claimed that this experience demonstrates the effectiveness of a sulphonamide even in the presence of pus, since the sulphonamide present as a contaminant in the pus prevented growth of susceptible organisms until neutralized by a P.A.B. substitute.

One of my assistants—Mr. A. Hodgson, F.I.M.L.T.—suggested this use of procaine.—I am, etc.,

Frank Marsh.

Artificial Respiration

Sir,—May I reply tersely to three recent criticisms in your columns?

(1) I had stated, "I am permitted to say that the proportion of successful resuscitations in the Royal Navy has increased since the rocking method was adopted." To this the Royal Life Saving Society replied (April 28, p. 618): ". . . we are given to understand on good authority that rocking methods are not being used in the Navy." Needless to say I could not have made this public statement unless the information was authentic and official: this has subsequently been confirmed.

(2) Dr. Clark Noble (May 5, p. 643) fails to see my point that—in a toneless victim lying prone in Schäfer's or the rocking methods—the upward thrust of the ground (or stretcher) immobilizes the ribs and anterior abdomen so that artificial respiration is effected almost only by the piston action of the diaphragm. (Anyone can feel the truth of this by lying prone on the floor.) Hence, if with approaching death in asphyxia the diaphragm also loses tone, Schäfer's method would be ineffective but the rocking method unimpaired. Dr. Noble concludes by saying that Schäfer's method is the most satisfactory. Yet surely he has read that in all the recent quantitative tests Schäfer's method has taken the last place, not the first.

(3) Surg. Rear-Adml. Cecil Wakeley (May 19, p. 712) quotes two distressing cases in which underwater explosion had caused perforations in the bowels. He blames the rocking method for causing wide escape of faeces, making operation hopeless. But what were the poor first-aiders on the rescue trawler to do? If breathing had stopped, death would quickly follow unless they promptly started artificial respiration. Schäfer's method would have been as bad as rocking in forcing faecal material through perforations, perhaps worse. Silvester's method is not admissible in blast cases because the lungs may be injured. Mouth-to-mouth inflation is the only harmless method in blast, but this is rarely taught (except for newborn babies) and the admiral omits to suggest it. Hence these two cases are not evidence that rocking has more contraindications than Schäfer's method; the reverse opinion is generally held.

The menace of the present situation (revealed in all three letters) is the false but tempting doctrine that Schäfer's method is invariably the best and all-sufficing. This saves instructors and administrators much thought and trouble but prevents all progress. Thank goodness, the Royal Navy in 1942 had the courage to point out the imperfections and bad overall results of Schäfer's method (though useful when single-handed or as a prompt preliminary to rocking). Ever since they have acted as pioneers towards more effective methods. For this grea task they have the finest facilities—teachers and taught anc rocking devices in the same ship. The aid of this *Journal* ha also been invaluable though impartial.—I am, etc.,

Hull. Frank C. Eve, M.D., F.R.C.P.

PS.—Prof. R. R. Macintosh (May 26, p. 747) considers tha as regards pulmonary ventilation, any method if given efficientl will probably suffice unless the patient is already dead. Bu this omits the great factor of circulation, which may decide th issue and in which the rocking method has shown its superiorit both experimentally and theoretically. And obviously, no on could tell whether a border-line case was already dead (i.e unrevivable) unless the *best* method had been tried properl and failed.—F. C. E.

The Child's Acquisition of Speech

Sir,—In her article on the child's acquisition of speec (May 19, p. 707) Dr. Mary Sheridan refers to so many sourcе of information besides her own interesting observations th it is all the more disappointing that in her closing remarks o "speech therapy" she leaves the reader with the impressio that failure in the development of speech in the young chil only needs investigation from the point of view of mental r tardation or organic hearing defect. Not infrequently, how ever, it is conditioned by emotional conflict. There may be n hearing defect, and speech therapy is in some cases found t be useless or inadvisable before the emotional difficulty h been adjusted.

In the case of a 4-year-old boy under my care with gro emotional disturbance, speech is returning parallel with resol tion of the emotional conflict.—I am, etc.,

London, W.14. J. E. Mackworth.

Final M.B. of London University

Sir,—There are people who consider that by allowing candidate to take the final M.B. in separate parts the standa is lowered. After a long experience as an examiner, I am co vinced the opposite is the case. When a candidate is oblig to take the two parts together and does well in one subject t examiners in the other subject (who are always humane) a liable to be persuaded to let him through the second subje although he is definitely below standard.

It is true that some candidates find it easier to attain t high standard of the M.B. by taking the parts separately, b is there really anybody against this, provided that he does rea that standard? I can find no evidence that a candidate w takes the parts separately will forget what he has learnt a quicker.—I am, etc.,

London, W.1. Malcolm Donaldson

Housing the Returned Consultant

SIR,—There are a few of us, now well advanced in the fifth decade of life, who in September, 1939, when we joined the Army uninvited, were serving on the honorary staffs of one or more of the London teaching hospitals. By virtue of our age and military service we have been led to hope for release from the Army in the near future. Our only means of living, before being caught in the net of a State medical service, is to subsist on the scanty ruins of our pre-war practices. Both custom and necessity urge us towards that citadel of consultants (and others) situated between Oxford Street and Marylebone Road. I am informed by a number of house agents who operate this area that consulting-rooms and living accommodation are impossible to obtain, and that for some rooms there is a long waiting list. One agent said despairingly, "There is Major-Gen. —— a major-general, no less, coming home and we have nowhere to put him." So there would seem to be little hope for those of us of slave rank. Rents are fantastic and Central Europeans abound in this chosen land. Perhaps eventually there may be an exodus of these foreign bodies directed by persuasion or compulsion to meet the medical needs of Germany, with which the R.A.M.C. are now contending. Many of us hope this may be so.

In the meantime could it be suggested to some benevolent medical body that a few houses be requisitioned for ex-Service consultants and specialists where rooms could be let at reasonable rents in which we could see our few patients and enjoy a sense of liberty and professional independence, at least for a time. The alternative seems to be to acquire a Nissen hut in the wastes of Regent's Park.—I am, etc.,

H. B. STALLARD, M.D., F.R.C.S.,
B.L.A. Major, R.A.M.C. (T.A.).

Indications for Adrenalectomy

SIR,—In your issue of May 19 two cases are recorded of adrenal virilism associated with mental changes treated by adrenalectomy. The first case (Clifford Allen and Broster, p. 696) showed a progressive schizophrenic psychosis and increased body hair growth with a "thick down" on cheeks, chin, and upper lip. There is no mention of the fact that the hirsutism was especially disfiguring or that the patient herself was sensitive of her appearance, and, indeed, if I interpreted the paper correctly, the psychosis and not the adrenal virilism was the main indication for adrenalectomy. The second case (Raymond Greene, Paterson, and Pile, p. 698) showed mental symptoms described as a "tense hypochondria," for the development of which there would seem to have been adequate domestic reasons, such as an alcoholic husband, an invalid mother suffering from hysterical fits, and a son whose asthmatic attacks often disturbed his mother's sleep. Subsequently acne and an inordinate growth of hair appeared. In this case the primary indications for adrenalectomy seem to have been the adrenal virilism, the rise in 17-ketosteroid excretion from 21 to 33.8 mg. a day, and the fact that a second perirenal insufflation gave an illusory appearance of increase in size of the left adrenal. In both cases removal of a normal-sized adrenal gland led to disappearance of the mental symptoms and improvement in regard to the hirsutism—"her hair could be easily pulled out" (Allen and Broster); gradual disappearance of the facial hair which had not been shaved, and no sign of further hair growth either on the shaven or unshaven areas (Greene et al.).

The publication of these two reports raises the question of the indications for adrenalectomy. Everyone would agree that in the presence of good evidence for the existence of an adrenal cortical tumour (such as palpation or visualization of the tumour, or an elevation of the 17-ketosteroid excretion to the region of 100 mg. a day) removal is essential and is usually followed by the disappearance of the virilizing features.

The indications for the removal of a normal-sized adrenal gland, however, are open to argument. It would, I think, be the opinion of those who have had experience of the treatment of superfluous hair in women that such an operation does not usually result in the cessation of growth of the offending hair. Indeed this impression is borne out by Broster himself, and he is undoubtedly the most distinguished exponent of adrenalectomy in this country. In his book *The Adrenal Cortex and Intersexuality* 28 cases of hirsutism without adrenal cortical tumour in which he has performed unilateral adrenalectomy are tabulated. Of the 10 cases in which the condition of hair growth at "follow-up" 4 months or more after operation is recorded, one only was apparently completely cured ("face free from hair" 9 months after operation). In the other 9 depilation was still necessary, though the hair "comes out easily." It would appear, therefore, that hirsutism by itself is not an adequate indication for removal of a normal-sized adrenal.

An elevated 17-ketosteroid excretion has been referred to in both the papers under discussion. At present, however, not enough is known about the normal range of 17-ketosteroid excretion to justify drawing conclusions as to the significance of values in the region of 30–40 mg., other than that they suggest that the adrenal glands are more active than normal—a suspicion which the hirsutism itself will have already established.

The pitfalls of perirenal insufflation, a procedure not completely devoid of risk, are brought out by the experience of Raymond Greene and his colleagues. Either this method of visualizing an enlarged adrenal or evidence of displacement of the kidney as provided by intravenous pyelography may, however, greatly assist in locating a suspected tumour after a very high 17-ketosteroid excretion has shown its existence to be likely.

There remain, therefore, only the psychological changes to be discussed as an adequate indication for unilateral adrenalectomy. Allen and Broster in their paper point out that they are recording the fourth case of schizophrenic psychosis associated with adrenal virilism, and that adrenalectomy should always be considered in this rare syndrome. Allen goes further, and indicates (in Broster's book) that many cases of adrenal virilism are associated with "abnormal sexuality" (e.g., autosexuality or homosexuality), and claims that "correction of the adrenal factor may lead to the restoration of normality." It may, therefore, be that adrenalectomy may come to be used as yet another heroic method of psychiatric treatment (like prefrontal leucotomy), concerning the justification for which I am quite unqualified to express an opinion.

Let us, however, be clear about one thing, and this is not stressed either in Allen and Broster's paper or in that of Greene and others—namely, that there is at the moment no evidence to show that removal of one normal-sized adrenal gland is justified in a woman with superfluous hair who does not show an "abnormal sexuality," a schizophrenic psychosis, or a "tense hypochondria."—I am, etc.,

London, S.E.1. P. M. F. BISHOP.

The Services

Col. (Acting) G. M. Warrack, R.A.M.C., has been awarded the D.S.O., and Capt. (Temp.) B. C. Montague, R.A.M.C., the M.C., in recognition of gallant and distinguished services in North-West Europe.

Capt. H. A. Cole, R.A.M.C., and Capts. M. Lerner and S. Worobetz, R.C.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in Italy.

Capts. A. C. V. Jones and E. H. Williams, R.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in Burma.

Safe and well in Rangoon.—Lieut.-Col. (Acting Colonel) K. P. MacKenzie, R.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Killed in action.—Capt. William Donald Wilson, R.A.M.C.

Wounded.—Lieut.-Col. G. E. Ord; Major B. McN. Truscott; Capts. J. W. Macmillan, M.C., H. R. Thomson, and W. H. McN. Wilson; War Subs. Capts. L. E. S. Coghlan, C. K. Hirson, G. Houseman, and H. M. Jones, M.C.; and Lieut. H. Holden, R.A.M.C.

Acting Squad. Ldr. JOHN NORMAN WILLIAMS died on May 10 of injuries received in an accident in N.W. Europe. He was born in May, 1915, studied medicine at Guy's Hospital, and qualified M.R.C.S., L.R.C.P. in 1939. He held house appointments at Belgrave Hospital, the Seamen's Hospital, Greenwich, and King George's Sanatorium, Liphook, and was appointed to a commission in the Medical Branch, R.A.F.V.R., in May, 1941.

Obituary

H. E. DUNNING GALE, M.B., B.S.

Surg. Lieut. Dunning Gale ended his life, aged 35, as a Marine Commando in the bitter struggle on the beaches of Dieppe in August, 1942. For over two years he was posted as missing, and news of his death has only recently come in.

Born in Monmouthshire on April 26, 1907, the preparatory school to which his parents sent him played a large part in shaping his career, for the family fortunes were in a poor way at that time and the headmaster took upon himself the education of two of the three Gale boys by coaching them privately before and after they had left his school. Fifteen years later, when Dunning was discussing his work as a doctor, he would seldom forget this debt that he owed to his old headmaster, Frank Barton.

Gale entered Bart's in April, 1927, and from the first his keenness for the scientific and laboratory side of medicine was apparent. In 1934 he was doing original work with Graham Weddell on changes in the blood-sugar level associated with surgical operations; work that was published, soon after he qualified, in the *British Journal of Surgery*. During his appointments as casualty house-physician at Bart's, and as house-physician to George Graham, his tough and stocky figure was well known about the hospital. With Graham he found he could blend his love for the laboratory with his interest in clinical medicine, and many were the nights one can remember when he was doing blood-sugar estimations long after the other residents were in bed. This was one of the happiest years of his life. His heart was in research, and for this his enthusiasm, patience, and thoroughness stood him in good stead. Under the late Prof. H. H. Woollard, F.R.S., and Prof. W. J. Hamilton, Gale at first enjoyed his anatomical work as demonstrator. He liked teaching and he was a good draughtsman. Prof. Hamilton writes: "In the transfer of the anatomy department from the hospital side to the new department in Charterhouse Square, Gale gave valuable service. In spite of heavy teaching duties in the department he found time to do research. He was particularly interested in tissue culture and had made progress in the developing of a technique for the growth of nerves *in vitro*. I always found him to be a very helpful and loyal colleague, ready and willing to give of his best. By his untimely death the medical profession has lost a young man of great ability and promise." After three years in the anatomy department Gale found that "teaching was not enough." His heart was in medicine, in his biochemical laboratory, and in clinical research; and in September, 1938, he resigned his appointment as demonstrator, and to everyone's surprise, except those who knew him well, he put his plate up in general practice in Bolton Gardens, S.W.10. Here, once more, he was happy. In a few months he equipped a clinical laboratory that was the envy of his colleagues, and in one short year he must have done more first-class clinical biochemical work than has ever been done before by a general practitioner. Single-handed, he carried out blood-urea, alkali-reserve, blood-sugar, and serum-protein estimations, urea-clearance tests, and many others, often working at them late at night, on top of all the manifold tasks demanded of him by a busy panel and private practice. His patients recognized at once that here was a young doctor out of the ordinary, with a good training, with modern ideas, and with first-class equipment, and many came to seek his advice. Those of us who were privileged to look after these patients when Dunning Gale was away, or after he had joined the Navy, knew what his patients thought about him, and about his keenness to give even the most humble of them—in their homes—the best that modern medical science could offer. It was his ambition to show that many uncomplicated laboratory investigations not only could but should be carried out by the practitioner himself. He believed that the future of medical practice lay in the more fully-trained practitioner investigating fewer patients more thoroughly.

Gale joined the R.N.V.R. in 1940. He was stationed on the South Coast during the Battle of Britain, and at this time he often used his car to rush to crashed machines, or to the aid of pilots who had baled out. Many times he was the first on the spot. When the call came for volunteers for the Marine Commandos, Gale offered his services, and so he came to be on the Dieppe raid. We are told by a comrade (who was, until recently, a prisoner of war) that, at the height of the fighting on the beach, Gale had a chance of getting back but he decided to stay with his wounded. Later he ran out from cover across a fire-swept beach to some wounded Canadians at the edge of the water, and there he met his gallant death. Of him we shall remember most clearly his enthusiasm in his professional work, his ready laugh, his deft fingers and fondness for "gadgets," his laboratory with its shelves of bottles, his microscope, his scientific outlook, and his loyalty to his friends. There are many who will feel in his death a particular loss.

J. H. H.

Dr. ELLIOTT BEVERLEY STEEDS-BIRD, well known as a radiologist in the Portsmouth area, died at Southsea on May 16, aged 64. He was educated at Cheltenham College and Trinity College, Dublin, qualifying L.R.C.P.&S.I. in 1903. After holding resident posts in Dublin he obtained the L.M. of the Rotunda Hospital in 1907. He served throughout the last war, was mentioned in dispatches four times, and received the D.S.O. in 1917 and the Territorial Decoration, and the Croix de Guerre Française, retiring with the rank of lieut.-colonel, R.A.M.C. He was proud of the fact that he went to France with the first Territorial contingent and was the first Territorial M.O. to command a regular field ambulance. Before his appointment as honorary radiologist to the Royal Portsmouth Hospital and the War Memorial Hospital, Gosport, Dr. Steeds-Bird had held the same post at the Royal West Sussex Hospital; he was also consultant radiologist to the Petersfield and Emsworth Cottage Hospitals. He joined the B.M.A. in 1910, was secretary of the Section of Radiology and Electrology at the Portsmouth Meeting of 1923, and was elected a Fellow of the Faculty of Radiologists in 1939. His principal recreation was sailing, and he belonged to the Royal Albert Yacht Club, Southsea, and the Royal Portsmouth Corinthian Yacht Club. Gardening and mechanics were also pursuits he enjoyed in his scanty leisure time. By his death the medical profession in Portsmouth has suffered a severe loss. His colleagues looked upon him as a true friend to whom they could always turn in trouble. During the war he was greatly overworked, owing to the absence of one of his partners in one of the Services and the enormous strain of extra duty among casualties both before and after D-day. A partner writes: Close personal and professional association with Beverley Steeds-Bird has been a great and rare privilege. Recent anxious and difficult years illuminated by his courage and comradeship became a precious experience, not to be missed, leaving happy memories. His never-failing sense of fun did much to lighten heavy work, and at times made even air raids almost enjoyable. Though one saw him every day, he never left the house but that one found oneself looking forward to his return. It has been easy to understand why he had a distinguished record as a soldier in the last war; easy to see why the nurses in his department at the hospital looked forward to his visits. It will not be easy to fill the gap caused by his departure.

Dr. ROBERT STEWART PARK, of Grove House, Paddock, Huddersfield, died with painful suddenness on May 13 while on a fishing holiday at Masham in North Yorkshire. Qualifying in 1908 at St. Andrews, he had been in practice for a few years at Silloth, interrupted by war service, and then in 1919 he settled in Huddersfield, where he speedily gathered a large circle of patients and conducted a very successful practice for 25 years. Although he took no part in public life, he was chairman of the Huddersfield Local Medical and Panel Committee for 13 years and on several occasions was the representative at the Annual Panel Conference. He was also chairman of the Huddersfield Division, B.M.A., and a prominent member of the Scottish societies which are features of English towns and cities. His wise counsel and natural Scottish caution were a great asset to the town, and he served with distinction on the Local Medical War Committee during the whole period of the European War, and was the most prominent member of the medical bureau, dealing with the accounts for evacuated children. His memorial service was attended by most members of the profession in the town, and his presence at medical gatherings will be sorely missed.—W. H. S.

Dr. HERBERT SHARPE, for twenty-one years medical superintendent of Ware Park Sanatorium, Herts, died suddenly a Bexhill on May 7. He was born at Peterborough on April 15 1883, and from Haileybury College went to Pembroke College Cambridge, and thence to Guy's Hospital after taking his B.A in 1906. He qualified M.R.C.S., L.R.C.P. in 1914 and serve in the last war as captain, R.A.M.C.(T.), with promotion to th rank of brevet major. Dr. Sharpe was then in turn assistan M.O. at Frimley Sanatorium, chief tuberculosis officer fo North Staffs, medical superintendent of King George's Sanatorium for Sailors at Liphook, and resident M.O. at the Hul Tuberculosis Sanatorium at Cottingham until his appointmen in 1923 to be superintendent at Ware Park. He joined th B.M.A. in 1919 and wrote two papers which appeared in thes columns, one of them reporting a case of primary actinomycosi of the lung.

Dr. JOHN DICK, medical superintendent of St. James' Hospital, Leeds, died on May 20, aged 51. After schoolday at Ayr Academy he entered the University of Edinburgh as medical student and graduated M.B., Ch.B. in 1915, and late took the D.P.H. His first appointments were as house physician and house-surgeon at the Edinburgh Royal Infirmar and he served during the last war with a commission in the R.A.M.C., attached to the King's African Rifles in East Africa. In 1920 he joined the staff of Fir Vale Hospital, Sheffield, and became deputy medical superintendent there. He left Sheffield on his appointment to Leeds in 1926. With the appropriations which took place under the Local Government Act of 1929 Dr. Dick had charge not only of St. James's Hospital but also of St. Mary's Infirmary, St. George's Infirmary, Cookridge Hospital, and, later, the institution which became known as St. James's North. He was a fine organizer and was largely responsible for the changes, extensions, and modern improvements which made St. James's the largest hospital of its kind in the country. Two of his brothers are medical men: Dr. James Hamilton Dick, of Bexhill-on-Sea, and Dr. Kenneth S. Dick, of Halifax.

Dr. BENJAMIN WAINMAN, who practised in Dewsbury Road, Leeds, for nearly half a century, died on May 14, aged 80. He was born on July 4, 1864, and studied medicine at the Yorkshire College, Leeds, taking the M.R.C.S., L.R.C.P. diplomas in 1889. He was police surgeon for the B Division of Leeds, 1914–23, and had served on the City Council for nine years and was chairman of the Leeds Public Health Committee. Dr. Wainman had been a member of the B.M.A. for 40 years, and he and his wife celebrated their golden wedding in 1944. Two of his children are members of the medical profession.—Dr. Wilfred Wainman and Dr. Leila Mary Wainman.

Dr. FRANK RAYMOND CROOKES, of Eckington, Derbyshire, died on May 9 after a long illness, aged 39. He was the only son of the late Dr. G. W. Crookes, of Eckington, and studied medicine at the University of Oxford and at Sheffield, graduating B.M., B.Ch. in 1930, and joining the B.M.A. soon afterwards. He entered the R.A.M.C. as temporary lieutenant in May, 1940, and was promoted war substantive captain a year later, retaining that rank when he relinquished his commission in August, 1944, on account of ill-health.

Universities and Colleges

UNIVERSITY OF OXFORD

n a Congregation held on May 3 the following medical degrees were conferred:

D.M.—*In absence:* F. Fulton.
B.M., B.CH.—J. P. Herdman, W. J. H. Butterfield, P. L. Skeggs, I. V. Polunin, I. J. Shaw, R. A. B. Drury, Susan A. J. Chappel, Janet E. Poulton, Jean M. Briscoe. *In absence:* C. L. Bulf, D. C. G. Bett, H. R. Morton, M. I. Bostock, I. D. Darcus, P. C. Elmes, G. R. B. McCarter, J. D. Judah, P. J. N. Cox.

UNIVERSITY OF CAMBRIDGE

At a meeting of the Senate held on May 8 to discuss a number of eports the Master of Trinity Hall (Prof. H. R. Dean, M.D.) said that the reports of the Council of the Senate and of the General Board recommending the establishment of a Department of Medicine nder the direction of Dr. R. A. McCance had been read with great pleasure by members of the Faculty of Medicine. The establishment in Cambridge of a department devoted to the advancement f medicine by research had been desired for many years. On the etirement of Sir Humphry Rolleston in 1932 from the Regius Chair of Physic the wish for a Department of Experimental Medicine was again expressed, and a few years later Sir Humphry's successor, Sir Walter Langdon-Brown, advocated the establishment of a chair in experimental medicine. On the appointment of Dr. Ryle to the egius Chair the University established a Department of Medicine, and in 1938 a Readership in Medicine was established for Dr. McCance. In 1944 the Interdepartmental Committee endorsed the proposals put forward by the representatives of Cambridge University for the establishment of a School of Clinical Research, to const of a number of units of which the first might be Departments of Experimental Medicine, of Radiotherapy, and of Psychiatry. It as the generous financial help of the Medical Research Council that had enabled the University to propose the establishment of the first of those departments. Prof. Dean was glad to put on record the appreciation of the Faculty of Medicine of the good will and co-operation with which the Governing Body and honorary staff of ddenbrooke's Hospital had met the proposals of the University, and also its lively satisfaction at the generous recognition which e M.R.C. had given to Dr. McCance's work.

At a Congregation on May 19 the following medical degrees were conferred:

M.D.—W. H. Mylechreest. M.B., B.CHIR.—*P. R. A. May. M.B.—*J. W. D. ttery.

*By proxy.

UNIVERSITY OF DURHAM

At a Convocation to be held in July the honorary degree of D.Sc. will be conferred on Sir Alexander Fleming, F.R.S., F.R.C.P., F.R.C.S., and the honorary degree of D.Hy. on Sir Wilson Jameson, M.D., F.R.C.P.

UNIVERSITY OF GLASGOW

At a special graduation ceremony to be held on June 26 a number of honorary degrees will be conferred, including the LL.D. on Major-Gen. Sir John Taylor, C.I.E., D.S.O., M.D., I.M.S.(ret.), late Director of the Central Research Institute, Kasauli.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

The Morison Lecture on "Recent Experiences in a Neuropsychiatric Division of Medicine" will be delivered by Mr. Norman M. Dott at the College (9, Queen Street, Edinburgh) on Friday, June 15, at 5 p.m. Medical graduates and senior students are cordially invited to attend.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

H.R.H. the Princess Royal, who is an Honorary Fellow, has sent a gift to the Royal College of Surgeons for the Restoration and Development Fund of the College.

The following lectures will be delivered at the College (Lincoln's Inn Fields, W.C.) at 4 p.m. each day. June 6, Arris and Gale Lecture by Dr. D. V. Davies, "Synovial Membrane and the Synovial Fluid of Joints." June 11, Arris and Gale Lecture by Prof. E. Davies, "Early Development of the Human Embryo." June 13, Hunterian Lecture by Air Vice-Marshal Geoffrey L. Keynes, "Surgery of the Thymus Gland." June 14, Hunterian Lecture by Col. Elliott C. Cutler, Hon. F.R.C.S., "Management of Battle Casualties." The lectures are open to medical practitioners and advanced students.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At a meeting of the Royal College of Surgeons of Edinburgh held on May 18, with Prof. R. W. Johnstone, President, in the chair, the following candidates, having passed the requisite examinations, were admitted Fellows:

F. E. D. Hallon, H. A. Hashemian, A. W. Khan, W. Laurence, M. R. Liddell, C. B. Limerick, J. W. Peden, A. L. Schofield, D. M. Sheppard, Betty V. Slesser, I. J. Thomas, M. E. Winston.

The Henry Arthur Dalziel Ferns Bursary was, after a competitive examination in organic chemistry in its application to medicine, awarded to M. C. Berenbaum.

COLLEGE OF PHYSICIANS AND SURGEONS OF BOMBAY

The Council of the College of Physicians and Surgeons of Bombay has placed on record its deep regret for the loss sustained by the death of Surg. Gen. Henry Wickham Stevenson, C.S.I., I.M.S.(ret.), who was one of its Foundation Fellows, a member and the first President of the College Council. The resolution states that it was on his suggestion that the constitution of the College was modelled on the lines of the Royal College of Surgeons of England. "General Stevenson was a man of broad views, various activities, and wide sympathies. It was he who had started the practice of Indianizing the Medical Services in the Province by appointing the late Dr. Y. G. Nadgir, an Indian and that too a non-I.M.S. man, as one of the full-time professors in the Grant Medical College in 1913. This had happened 32 years ago, when the idea of Indianization of the Services was not properly conceived and much less practised."

Medical Notes in Parliament

Mr. Churchill on May 23 tendered his resignation to the King and was entrusted with the formation of a new Government. All members of the old Government went out of office with the Prime Minister. Parliament is to be dissolved on June 15. A General Election will follow on July 5.

Teeth of School-children

On May 15 Mr. LINSTEAD asked the Minister of Education whether, in view of the bad condition of the teeth of school-children, as evidenced by the findings of the Interdepartmental Committee on Dentistry, he would consider the appointment of a dental surgeon on the central advisory councils set up by the Education Act, 1944, in order that the development of the school dental service and of education in the care of teeth might be kept in the forefront of educational reforms. Mr. BUTLER: While I am fully alive to the importance of the school dental service, I do not see my way to increase the membership of either of the central advisory councils.

Future of National Service

Intervening on May 16 in a debate on the resettlement of Service personnel and war workers, Mr. **ERNEST BEVIN** said the nation would probably have to face for a number of years national service of some kind or military training. There were 1,000,000 men over 65 and women over 60 in industry. The war had naturally taken its toll of these. The number of juveniles now available to go into industry was reduced because of the heavy fall in the birth rate between 1922 and 1930. The nursing profession gave him great anxiety. The Ministry of Labour would make efforts to induce women coming out of the Forces and others to take up nursing training, which the Government was ready to assist financially in order to build up a nursing force. Many nurses were wanted urgently for Burma and the Far East. With regard to the relaxation of controls, men over 65 and women over 60 would be allowed to leave their jobs and not be required to take others. Women over 50 would be allowed to leave their jobs unless it was vital for them to remain. Women over 40 would no longer be called up for interviews and women under 21 would no longer be required to leave home.

Negotiating Committee

Dr. **HADEN GUEST** asked on May 17 whether the Minister of Health had any statement to make on the results of his discussions with the Negotiating Committee of the medical profession on the National Health Service. Mr. **WILLINK** replied that he did not think he could usefully make any statement at that stage.

Mr. **WILLINK** announced on May 17, in answer to Dr. Haden Guest, that he would at an early date meet the Negotiating Committee, possibly for the last time at this stage. He said he would then be in a position to relate their views to those of the local authorities and to discuss the matter with his colleagues. Dr. **SUMMERSKILL** asserted that enlightened medical associations regarded with disfavour these negotiations which were being conducted behind the scenes. Dr. **MORGAN** said it was in perfect order, and an established trade union practice in any organization of workers, medical or other, for reports not to be required during the negotiations.

Freed Channel Islands

Reporting to the House of Commons on May 17 after his visit to the Channel Isles, Mr. **HERBERT MORRISON** said the health and physique of the population there were better than he had dared to hope. He had been impressed by the healthy appearance of the children. This was largely due to the supplies which during the past winter the islanders received from the British Red Cross and Order of St. John through the International Red Cross. So far as he could ascertain, the Germans had not attempted to divert the Red Cross supplies. The Germans had left the premises they had occupied in a filthy condition. That was even true of the hospitals. He could not say whether there was an adequate supply of doctors in the Islands. That difficulty had not been mentioned to him.

Mr. **KEELING** asked whether Mr. Morrison would give island doctors priority to return. Mr. Morrison did not reply.

Mental Institution Nurses

Mr. **JOHNSTON** announced on May 17 that the chairman of the Scottish Nurses' Salaries Committee had given him a summary of the recommendations on which the Committee had agreed up to that date. The summary recommended scales and salaries for male and female mental institution nurses up to and including the charge nurse or ward sister. It also made recommendations on hours of work, annual leave, and sick pay. A circular was being sent to all employing authorities commending adoption of the Committee's recommendations. He hoped soon to present to Parliament a complete report from the Committee on the salaries and conditions of service of nurses in mental institutions.

Shortage of Doctors in Evacuation Areas

Sir **HERBERT WILLIAMS** asked on May 17 if Mr. Willink's attention had been drawn to the shortage of doctors in many of the evacuation areas and what steps were being taken to reinforce the strength of the medical profession in those districts to which many evacuees would soon return. Mr. **WILLINK** replied that any special shortage of doctors caused by movements of population of that kind was a matter for consideration by the Local Medical War Committee for the area. After taking account of any doctors coming into the area, either on release from the Forces in an early demobilization group or otherwise, it would be open to the local committee to apply through the Central Medical War Committee for the special release of a doctor where the circumstances of the area justified that course.

Ministry of Health Appointments

Mr. **WILLINK** stated on May 17 that one pensioned medical officer from the R.A.F. had been appointed to the Ministry of Health during the past 12 months. He had since resigned. Such appointments were made on a temporary basis pending the resumption of normal permanent recruitment. Four pensioned medical officers from the R.A.F., one of whom had resigned, had been appointed to temporary posts in the Ministry of Pensions during the same period.

Dietetic Advice for Repatriates

Mr. **ARTHUR HENDERSON** told Major Gates on May 17 that not all repatriated prisoners of war were in need of special dietetic advice. It was given orally by medical officers at reception camps to those who needed it. The latter also distributed as necessary a printed leaflet, which contained hints on diet during recuperative leave for those whose digestion had been impaired by their privations in captivity, and advice on which types of food were suitable and unsuitable and on the size and timing of meals. It was not thought necessary to provide repatriates on leave with elaborate charts specifying quantities of foodstuffs that should be eaten. Any man requiring such a carefully regulated diet would be admitted to hospital before being sent on leave.

Treatment of Mental Illness in Service Patients

Mr. **WILLINK**, replying to Mr. Messer on May 17, said members of H.M. Forces suffering from mental illness were dealt with by the medical services of the Forces. Some accommodation in civilian mental hospitals had been especially assigned to those services for the purpose. In the neurosis centres provided under the E.M.S. there were, on March 31, 994 males and 149 female Service patients. After-care of members of the Forces discharged from neurosis centres as well as from mental hospitals was undertaken by the Provisional National Counci for Mental Health in collaboration with the Mental After-Car Association.

Cost of Deaf Aids.—On May 8 Mr. **KIRBY** asked the Presiden of the Board of Trade if his attention had been drawn to the numbe of men and women who had become deaf during the period o heavy bombing; and whether, to assist those who desired to obtai deaf aids, he would have inquiries made into the high cost of thes appliances. Mr. **DALTON** said that the Central Price Regulatio Committee was examining this matter in consultation with th Electro-acoustics Committee recently set up by the Medical Researc Council.

Requisitioned Harley Street Houses.—Sir E. **GRAHAM-LITTLE** o May 16 drew attention to the shortage in the Harley Street area o consulting-rooms used by medical consultants, through requisitionin of houses by the fighting Services. He asked the Secretary of Stat for War to release as many of these premises as possible, in vie of the early return of consultants from war service. Sir **JAMES GRIG** said the War Office had requisitioned three houses in Harley Stree Two of them were occupied, the third would be occupied whe alterations had been completed. He was at present unable to releas any of these houses.

Medical Examination before Courts Martial.—On May 15 M **TURTON** asked the Secretary of State for War whether soldiers wer examined by a psychiatrist before being tried by field general court martial. Sir **JAMES GRIGG** said that before such a trial a man wa always examined by a medical officer, but not necessarily by psychiatrist.

Cholera among British Officers in Calcutta.—Mr. **AMERY** said o May 17 that fifteen cases of cholera occurred at the end of la month among the British officers billeted at a hotel in Calcutta. C these one died as a result of developing pneumonia. Three of th waiters were afterwards discovered to be cholera carriers. In mediate action was taken and the outbreak was at an end. I Burma there had been 26 sporadic cases of cholera, mostly amon Indian troops. There had been no other cases of cholera amon British troops in India and Burma since 1943. As cholera w endemic in these areas the comparative immunity of the troo was a tribute to the skill and devotion of the medical services an the value of modern protective measures.

Leprosy in Britain.—In this country 22 cases of leprosy have bee brought to notice during the war, of which 9 have been in perso known to be British subjects.

Public Health Laboratory Service.—The provision of a publ health laboratory service on a national basis after the war and t form which any such service should take are matters which a under consideration as part of the wider proposals for a compr hensive health service.

Medical News

Lord Horder will deliver the third Sanderson-Wells Lecture at the Middlesex Hospital on Wednesday, June 6, at 4 p.m. The subject is "Food and Rheumatism." Members of the medical profession are cordially invited to attend the lecture.

A meeting of the Nutrition Panel of the Society of Chemical Industry will be held at the Rooms of the Chemical Society, Burlington House, Piccadilly, W., on Wednesday, June 6, at 2.30 p.m., when a paper on "Protein Hydrolysates—Their Preparation and Clinical Uses" will be read by Dr. D. P. Cuthbertson. A discussion will follow.

A clinical meeting of the Middlesex County Medical Society will be held at the North Middlesex County Hospital at 3 p.m. on Saturday, June 9.

The lecture by Dr. F. M. R. Walshe on "Infantile Paralysis," to be given before the Royal Society of Arts, John Adam Street, Adelphi, W.C. (postponed owing to VE holidays) has now been arranged for Tuesday, June 12, at 1.45 p.m.

At the meeting of the Board of the Finney-Howell Research Foundation on March 2 fellowships were renewed for a third year for Dr. Nelicia Maier; for a second year for Drs. Muriel Virginia Bradley and Margaret Aston Kelsall; and a new fellowship was awarded Dr. Elizabeth Cavert Miller, to work at the University of Wisconsin. Applications for fellowships for 1946 must be made to the office of the Foundation (Medical and Chirurgical Faculty Building, 1211, Cathedral Street, Baltimore, Md.) before December, 1945, to be eligible for consideration.

The Minister of Health has notified all local authorities and port health authorities that a photographic display is now available for use in the educational campaign against venereal diseases. This display tells frankly what the venereal diseases are, how they are caused, what are their effects, and why skilled treatment should be obtained at the earliest possible stage. It has been prepared for private showing to those who wish to see it, and to members of the two sexes separately; it is being offered by the Ministry of Information to factories throughout the country. Copies on free loan are available to local authorities through the Central Council for Health Education.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* most infectious diseases fell in incidence during the week, the drops being as follows: measles 727, whooping-cough 251, dysentery 126, diphtheria 91. Two cases of typhus fever were imported into the country.

The chief local variations in the trend of diphtheria were decreases of 28 in Yorks West Riding, 23 in Staffordshire, and 14 in Northumberland, and a rise of 9 in London. The decline in whooping-cough was fairly general throughout the country; Yorks West Riding showed a decrease of 36. Although the notifications of measles fell substantially, there was a rise in several counties, particularly in the south, where notifications were higher than last week by the following numbers: Northamptonshire 174, Sussex 113, Dorsetshire 83, Berkshire 71, Wiltshire 64, Middlesex 62; Southampton reported 280 fewer cases, Monmouthshire 207, Glamorganshire 206, Lancashire 114, and Gloucestershire 106.

The notifications of dysentery fell for the third week, but the incidence is still high—343. The largest returns were Lancashire 63, Staffordshire 39, Yorks West Riding 30, London 25, Kent 19, Surrey 18, Essex 18, Gloucestershire 16, Warwickshire 14, Middlesex 10.

In *Scotland* measles showed 152 fewer notifications than last week, whooping-cough 74, and dysentery 61, but there were 36 more cases of pneumonia, and 25 more of diphtheria. The largest returns for dysentery were Aberdeen 22, Edinburgh 22, Dundee 13, Glasgow 12. The recent large outbreak in Aberdeen, involving 245 cases in the King's Gate district of the city, had its origin in a dairy.

In *Eire* the chief feature of the returns was an outbreak of dysentery in Monaghan U.D., involving 20 persons.

In *Northern Ireland* there were 19 fewer notifications of scarlet fever, 10 fewer of whooping-cough, and 9 fewer of measles; there was a small increase of 3 in the incidence of diphtheria.

Week Ending May 19

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,340, whooping-cough 1,068, diphtheria 498, measles 14,126, acute pneumonia 612, cerebrospinal fever 64, dysentery 434, paratyphoid 2, typhoid 2, typhus 7 (imported cases).

No. 19

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended May 12.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

Rate per 1,000 total births (including stillborn)			40					33		

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to The Editor, British Medical Journal, B.M.A. House, Tavistock Square, London, W.C.1. Telephone: EUSTON 2111. Telegrams: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). Telephone: EUSTON 2111. Telegrams: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. Telephone: EUSTON 2111. Telegrams: *Medisecra Westcent, London.*

B.M.A. Scottish Office: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Motor Nerve Supply to Tongue and Lips

Q.—*What is the embryological explanation for the motor nerve supply to the tongue and lips (i.e., the most "anterior" part of the alimentary canal) being via the 12th cranial nerve, yet the pharynx, larynx, etc., more distal parts of the alimentary canal, are supplied by the 9th and 10th nerves?*

A.—The comparative study of anatomy shows that the tongue musculature was evolved by forward extension of ventral neck musculature into the floor of the mouth: like the infrahyoid musculature it is thus a derivative of the body wall (somatic) musculature. Now it has been established in various submammalian animals that this ventral neck musculature is developed in the embryo from certain myotomes. In man, however (as perhaps in mammals generally), the process of development has been modified and it is differentiated *in situ*. It is nevertheless innervated in man by a nerve, the hypoglossal (closely associated with the ansa hypoglossi), which has a course and central connexions that identify it with the nerves which supply the ventral "neck" musculature in fish, amphibians, and reptiles—i.e., it is a somatic motor nerve in series with the ventral (anterior) roots of spinal nerves. The hypoglossal nerve, again, has a rudimentary dorsal ganglion in embryos (including the human), which observation emphasizes the comparison with spinal nerves.

The musculature supplied by the 9th and 10th nerves develops as a part of the wall of the pharynx in man, as in fish. These nerves in man leave the skull above the hypoglossal nerve, and the relation is similar in fish (the equivalent to the hypoglossal nerve is commonly known as the "hypobranchial" nerve in fish). The inquiry resolves itself, then, into an inquiry concerning the arrangement in fish. Now it is known that in fish and amphibian embryos a number of myotomes become suppressed at the anterior end of the series, in the posterior head region, and that the hypoglossal nerve loses some of its more cephalad rootlets in the course of development. The hypoglossal nerve is, then, presumed to have had an origin (in the central nervous system) which originally extended further forwards and overlapped the 9th and 10th nerves.

The explanation of the backward extension of the 10th nerve as far as the intestines is obscure. The human arrangement obtains also in fish. This part of the vagus contains autonomic fibres of the cranial outflow, which are distributed to a region that is also supplied from the thoracic outflow. The distribution of the autonomic system does not therefore follow so clear-cut a segmental pattern as that of the nerves of the body wall. A similar problem is afforded from the distribution of autonomic fibres from the thoracic outflow to various structures in the head.

The actual numbering employed for cranial nerves was based on the early accounts of human anatomy. It is well known that it does not well express the pattern of the cranial nerves; namely, there is a cranial nerve, the "nervus terminalis," in advance of the 1st or olfactory, and the 11th might well be described as a portion of the 10th. The generally recognized enumeration must be retained for convenience.

Skodaic Resonance

Q.—*Skodaic resonance, an area of resonance on percussion, is sometimes found over a pleural effusion. This is said to be due to relaxed lung tissue. How can the lung tissue be relaxed over a pathological process which is "pressing on" the lung? Has any other explanation been put forward?*

A.—Skodaic resonance is found over the lung immediately *above* an effusion, not *over* the effusion itself. The normal lung is an elastic organ and is stretched to fill the pleural cavity; when part of that cavity is occupied by fluid the lung is at first relaxed. This relaxation is said to be responsible for the peculiar "boxy" note heard on percussion above an effusion. When the fluid fills the pleural cavity the lung becomes completely collapsed and finally compressed. The percussion note is then dull, but very occasionally hyper-resonance can occur over a chest full of fluid. Bosanquet (*Brompton Hosp. Rep.*, 1937, **6**, 59) described two examples of this rare phenomenon and the writer has seen one other; the cause is unknown.

Calcium in Water

Q.—*The water in this district (Scopwick, Lincoln) is so heavily charged with calcium carbonate that particles may be seen floating on the surface of water that has stood a short time; kettles are heavily encrusted with the salt. What is the modern opinion of the effect this water has upon the body? Constipation is a definite result to those visiting and unused to the water: I have never experienced greater "hardness" anywhere else in England, and I have lived in many areas.*

A.—The furring of kettles and boilers and the wastage of soap are the chief disadvantages of a very hard water. Even if the water is extremely hard it is unlikely to contribute more than 200 mg. of calcium to the daily intake, which usually runs between 600 and 1,500 mg., and this addition is beneficial rather than harmful. The hard water is unlikely to be responsible for visitors' constipation. In this connexion one must remember (*a*) that a change of diet and habitat is very liable to make a person constipated for a few days and (*b*) that people are very prone to make something like the water, with obvious drawbacks, the scapegoat for their minor medical maladies.

Prostigmin in Arthritis

Q.—*Can you give me any information about the use of prostigmin to relieve pain in cases of rheumatoid arthritis? Is it of any use in osteo-arthritis?*

A.—The claim has been made that injection of prostigmin combined with atropine relieves the pain of rheumatoid arthritis, and the writer has had the opportunity of testing this in a limited number of cases. Where the pain is due to spasm of the muscles associated with affected joints relief is given because the effect of the drug is to relax spasm, but in the absence of spasm (and it is not a common feature in true rheumatoid) better results are obtained by the use of the more common analgesics such as aspirin, phenacetin, codeine, etc., alone or in combination. In cases where cramp is a troublesome feature prostigmin has also given prompt relief, but the writer has not been able to keep such cases under observation for long enough to say how lasting the relief may be. It is therefore reasonable to give prostigmin and atropine where spasm is present, but when the spasm has relaxed it is desirable to prevent its recurrence by suitable physical measures, such as the application of light splints, rather than to continue the administration of such powerful drugs which have been observed to produce undesirable effects if administration is prolonged.

The use of prostigmin was advocated in an American medical journal and the article was quoted in a popular magazine; but in the first case in which dramatic results were obtained and which is described the condition was quite obviously not rheumatoid arthritis but subacromial bursitis, in which the pain is much more severe than in arthritis and is directly due to spasm; of the other cases described some were probably rheumatoid, though the description was not very scientific, while at least one was of a different nature. This being the case, the article fails to carry conviction, and further investigation is required.

"The Sweats"

Q.—*Is anything known or surmised about the aetiology of the sweating sickness which was apparently so very common in the fifteenth and sixteenth centuries and from which Charles Churchill (the poet died in 1764? It seems from various historical works that it was at times widespread and extremely fatal. Has any conclusion, other than that it might have been a virus infection, been reached?*

A.—The late Sir William Hamer (*The Milroy Lectures on Epidemic Disease in England—The Evidence of Variability and of Persistency of Type.* 1906. London: Bedford Press) gave reasons for thinking that the sweats were epidemics of influenza—an opinion which is probably held by most epidemiologists of this generation, although naturally, the reasoning is wholly by analogy. Suggestive points are: (1) rapid diffusion, (2) general symptoms, (3) lack of evidence that the underfed and overcrowded classes suffered more than the well-to-do—evidence plentifully obtainable in other plagues of ancient times.

Hallux Valgus

Q.—*What is the prognosis of arthroplasty excision of base of phalanx for hallux valgus in a female 65 years old? Does age affect the outlook? What is the period of incapacity, and should one recommend surgical treatment at this age?*

A.—In a patient of 65 a hallux valgus is likely to be but a part of a widespread foot disturbance with a good deal of splaying of the metatarsals. Removal of the base of the phalanx at this age will do little to remedy this. The patient will get more relief from the use of appropriately shaped pads and metatarsal straps, such as could be fitted by a properly qualified chiropodist. In patients of this age the only indication for operation would be a local pain caused by a recurrent bursitis or an osteophytic outgrowth, and the operation should be the smallest possible—i.e., removal of exostosis and bursa, and so on. Even so, the condition of the circulation in the foot should be carefully ascertained beforehand and no operation undertaken unless it is satisfactory. Local gangrene and delayed healing may follow quite simple operation on the toes in older patients.

There is a tendency to underestimate the period of incapacity which follows operation upon the great toe. It would probably be wise to estimate that six weeks will elapse before the patient is able to wear ordinary shoes.

Physiology and Psychology of Craving

Q.—*Can any reader tell me what is the cause of a "craving," for any special food, drink, or smoke? What are the conditions precedent to such a state (is it?) of mind?*

A.—As a psychologist, I should first of all look for a physiological cause. We do not know enough about biochemistry to detect *any* chemical deficiency; but we do know that the hypoglycaemic child is the one who craves for sugar—because he needs it. Piglets, immediately they are released from the spotlessly clean sties, rush to eat earth, not because they like earth as such, but because they need the iron in it. A craving for pickled onions may be an aid to digestion in the intestinal canal. It is to be remembered that when the body had need of some such food, it feels the need for it although it has no knowledge of what it needs.

The psychopathologist more commonly meets with the *dislike* for certain substances, such as milk or lettuce, and in such cases this can usually be traced back to experiences in childhood, when either too much was forced on the child, or the child choked with the skin on the milk, etc. On that analogy one would expect that a craving of psychological origin would be due to the association of that food with pleasure, probably of a very fundamental kind, such as of a person greatly loved in childhood, or of a strong sensuous gratification.

We have not met a craving for a specific type of tobacco with a refusal of all others, but the craving to smoke, and chain smoking in particular, which is often more difficult to give up than alcohol, s usually traceable to the persistence of disorders or exaggeration of the sucking tendency in infancy. But it is an activity which starts in the boy or girl as a desire to be grown up, and therefore, like other forms of neurosis, compulsive smoking gratifies two opposing tendencies—the infantile and the adult—not to speak of ts soothing narcotic effect, which is partly infantile. I have a patient at the moment who has the craving to light a cigarette and take a few puffs, but who then throws it away; this refers back to a craving for, but rejection of, the mother's breast.

Is a Toothbrush a Good Thing?

Q.—*What evidence is there that cleaning the teeth with a toothbrush is a good thing? Does the modern view support the statement that "the use of a toothbrush saves the teeth at the expense of the gums"? The best teeth I have seen, and the only jaws with 32 healthy teeth, have been in those who have never used a toothbrush.*

A.—The use of the toothbrush is an essential habit for everyone who wishes to have healthy teeth and gums. Brushing the crowns of the teeth removes debris and keeps the surfaces polished and thereby minimizes the risk of decay. Places, such as the interdental spaces, where the bristles cannot reach are always the danger spots for the commencement of decay. But just as important is the good, not harm, derived from brushing the gum margin. The secret for healthy gums is friction of the margins by the toothbrush, which keeps the epithelial surfaces well keratinized and prevents the onset of pyorrhoea. There are other methods of cleaning the teeth and gum margins, but the toothbrush must be given priority. For every person with thirty-two healthy teeth who have never used a toothbrush there must be ninety and nine who are ursed with no teeth at all by the time they have reached middle age.

Malignant Cells in Sputum

Q.—*What is the technique for the demonstration of malignant cells in sputum in the diagnosis of carcinoma of the bronchus?*

A.—The method generally used for this purpose was described by the late Prof. L. S. Dudgeon (*St. Thom. Hosp. Rep.*, 1936, **1**, 51). From a fresh specimen of sputum the more cellular portions are selected—especially any which are blood-stained—spread on a slide, and fixed while still wet in Schaudinn's solution. After treatment with methylated spirit to which a few drops of tincture of iodine have been added, and washing in water, the film is lightly stained with Mayer's haemalum (about 2 minutes), left in tap water until blue, counterstained with eosin, and dehydrated and mounted in balsam in the usual way. The questioner should refer to Dudgeon's paper for an account and illustrations of the appearances of clumps of malignant cells in the sputum. He will also be well advised to examine a considerable number of specimens from patients with and without cancer of the lung before venturing to affirm that he has identified malignant cells. This is difficult even with experience, and mistakes have been made. It is no doubt for this reason that many pathologists are reluctant to attempt this examination.

Radiotherapy for Dupuytren's Contracture

Q.—*Is there any evidence that radiotherapy is of value in the treatment of Dupuytren's contracture?*

A.—Radiotherapeutic technique is always a difficult matter to write about. It is so liable to smack of "prescribing by post," whereas, of course, innumerable factors of clinical experience come into it when dealing with each particular patient. However, I would say that the answer to the above question is yes: in the early case both subjective and objective improvement is obtained. My own technique is by fractional doses over 10 days to produce a first-degree erythema.

Quarantine for Measles

Q.—*What is the necessary period of quarantine for measles? The Board of Education lay down this period as a minimum of three weeks from the appearance of the rash. The Medical Officers of Schools Association booklet lays down ten days from the appearance of the rash.*

A.—Infectivity of measles is highest in the pre-eruptive stage and thereafter wanes rapidly. The period over which the virus remains viable and infective in any given case is probably determined by the amount of upper respiratory catarrh which accompanies the attack. Thus, in measles well modified by serum quarantine of no more than 4 to 5 days is necessary. At the other end of the scale clinical experience indicates that a sharp attack of measles with pronounced catarrhal features or accompanied by coincident respiratory infections such as whooping-cough, influenza, etc., may remain mildly infectious up to 12–14 days from onset. Thus, a period of 10 days from the appearance of the rash provides very adequate quarantine for all cases.

Corneal Scar

Q.—*In the* JOURNAL *of April 28, in an answer about a contact lens for corneal scar, your adviser hints at "more simple and less expensive methods." What alternative would he suggest to obtain the maximum optical efficiency?*

A.—Where one eye interferes with the vision of the other, the following are the usual methods of obtaining relief: (1) a ground glass in the appropriate spectacles in front of the interfering eye; (2) a "clip-on" opaque disk similarly placed; (3) a Chavasse glass (i.e., a crinkled glass) so that the cosmetic appearance is altered as little as possible.

INCOME TAX

Pension: Claim for Expenses

F. S. is in receipt of a pension as from the death of her husband on active service. Can a claim be made (*a*) for insurance (endowment) and (*b*) for cost of storage of furniture, which was necessitated by enemy action?

⁂ (*a*) Yes, if the insurance is on the life of F. S. (*b*) No—there being no assessed income against which such cost can be off-set as a relevant expense.

University Scholarship

M. P. qualified two years ago and has now been granted a scholarship of £110 per annum. Is this liable to income tax?

⁂ Section 28 of the Finance Act, 1920, provides that income arising from a scholarship held by a person receiving full-time instruction at a University . . . shall be exempt from income tax. If any doubt arises as to whether a particular scholarship comes within the section, the Commissioners of Inland Revenue are authorized to consult the Board of Education on the point. M. P. might ask the university authorities whether the point has been decided in connexion with a previous holder of this scholarship.

Locumtenent and Travelling Expenses

J. D. sends an inquiry of a general nature.

⁂ In our opinion a locumtenent working for short periods in different areas during a financial year is normally to be regarded as exercising his profession in such a way as to bring him under Schedule D and to entitle him to all expenditure incurred "wholly and exclusively" for the purposes of his profession, including the expense of travelling from his residence to the places where he does his professional work. The correspondent to whom J. D. refers worked for one employer under terms which brought the earnings within Schedule E. That Schedule, in spite of the more stringent rule with regard to expenses, was preferable for the year concerned in the taxpayer's interest, and furnishes no guide as to the line to be taken in the usual type of locumtenency engagement.

LETTERS, NOTES, ETC.

Examinations in Stages

Mr. G. H. COLT, F.R.C.S. (London, W.1), writes: A surgeon who is well known to me was able to prepare for and make one serious attempt at passing the Final F.R.C.S. examination. He failed in one of the six parts. From then onwards he took passing shots at the examination each time it came round, but without further preparation. Each time for five times he failed in one of the six parts, and each time it was in a different part, so that in all six attempts he failed once in every part. At the seventh attempt he drew winners in all the six parts, and being freed from thraldom has become a real surgeon in the Near East. The facts given show how examinations and examiners may fail when, in the so-called higher degrees, the element of chance becomes greater than the element of ability to show one's knowledge. Examinations which hinder rather than help a prospective surgeon in the preparation for his life's work should be abolished There are excellent alternatives for testing a candidate's surgical ability, and these are safer for the public, at any rate at the start of his career!

A New Covering for Skin Dressings

Dr. R. STOPFORD-TAYLOR (Liverpool) writes: I was very interested and glad to read in the *Journal* of April 7 (p. 485) that Dr. J. E. M. Wigley had found a new use for perforated oiled silk. I would remind him; however, that the idea of using "green protective with holes" for the treatment of granulating surfaces following burns was suggested over 30 years ago. Perforated oiled silk has been freely obtainable through the usual channels of surgical supplies for over ten years. It has been perfectly satisfactory, and there is no doubt of its value as a semi-occlusive and painless dressing. I drew attention to its use in the treatment of burns in a clinical memorandum in the *Journal* of March 15, 1941 (p. 403).

Unilateral Flush after Food

Dr. A. D. McDWYER (Dublin) writes: In the question under the above title (May 12, p. 687) the account of a transient facial erythema, appearing at the beginning of a meal and vanishing in 1/2 to 3/4 hour afterwards, seems to show a very close relationship to the auriculo-temporal syndrome, if it is not essentially the same. This syndrome, which has been the subject of reports in the literature for over half a century, is characterized by redness followed by sweating, of one side of the face: although the two areas may not have the same extent. The vasodilatation may be accompanied by very mild pain. Objective alterations in sensation in this area innervated by the auriculo-temporal nerve may be elicited. The vaso-cutaneous manifestations are produced reflexly by tasting rather than chewing, especially spicy foods and also psychically by the sight of any procedure with food which stimulates the parotid gland to activity. In a large proportion of cases, if not all, there is a previous history of trauma in the region of the parotid gland, or of parotitis, usually complicating one of the infectious fevers.

To understand the theories of causation a short account of the anatomy will be of value. The auriculo-temporal nerve, a branch of the third division of the trigeminal, receives a communication via the otic ganglion from the glosso-pharyngeal nerve, conveying secretory fibres to the parotid gland, and then pierces the latter, to supply the skin over the temporal area, part of the pinna, and over the parotid gland. This nerve also receives a branch from the cervical sympathetic trunk, and a twig from the seventh nerve. It is suggested that subsequent to injury or parotitis there is increased formation of fibrous tissue around the nerve, which becomes compressed from the swelling of the gland when the latter is stimulated into activity. Vasodilatation and sweating are the consequence of this pressure on the vegetative fibres. Another theory is that the nerve is injured, either from trauma or from parotitis, and in the subsequent regeneration the glosso-pharyngeal fibres become diverted from their purpose of supplying the parotid gland. The third view is that this phenomenon is an exaggeration of the appearance normally seen in this area on a person's face when eating. The first suggestion is the most favoured, and, as this condition has been present since birth, the possibility may be that the aetiological cause was trauma during delivery. I am not aware of any satisfactory treatment, but if the symptoms are troublesome irradiation has been suggested (W. Needles, *Arch. Neurol. Psychiat.*, Chicago, 1936, **35**, 357). In view of the causation, could this really be wise?

Yaws and Positive Kahn

Dr. G. SHEARER (Colonial Medical Service, Nigeria—on leave) writes: I read with great interest the answer to the question on "Yaws and Positive Kahn" in your issue of April 14 (p. 543). Having studied the problem of yaws closely there are certain parts of the answer I would like to comment on. I was glad it was emphasized that yaws was not endemic all over West Africa, and that in areas where it was not endemic syphilis is common. In some colonies yaws is endemic in some areas of the colony and not in others. In Nigeria, for example, yaws is endemic throughout the south, whereas in the north it is unknown, but syphilis is rife. Humidity as well as heat is a predominant factor in determining the endemic yaws areas.

The statement that the Kahn test may be rendered positive by leprosy, malaria, and trypanosomiasis is open to argument. In regard to trypanosomiasis, I think the statement is inaccurate. My colleague Dr. C. W. Hope Gill published an article in the *Journal of the Royal Society of Tropical Medicine and Hygiene* about 1931 showing that the Kahn test is not affected by that disease; and, following on his work in the area where yaws and sleeping sickness were both endemic, I had ample reasons to confirm his findings. A certain amount of work on the effect of leprosy on the Kahn test has been done lately at a leper colony I know, but nothing has been published yet. It would be premature to make pronouncements on it, but I am led to understand that the opinion formed is that the effect of leprosy on the Kahn test is so small and rare as to be of no importance whatsoever. As to malaria affecting the Kahn test, the suggestion is new to me, and I would like to be given some indications as to the authority for this statement.

In the answer given it is stated that "if a positive Kahn is due to yaws a couple of short courses of N.A.B. would almost certainly reverse it," and I agree entirely with this; but I fear the cases thus treated would come into the category of inadequately treated yaws infections, as the Kahn test would probably not remain negative. Too much has been said and written about curing yaws with one o two injections of N.A.B. If we are to take the disappearance of symptoms and external signs as a cure, then this is correct; but, to be logical, the disappearance of the primary sore in an early case of syphilis would be regarded as a cure of that disease. The only criterion of cure in yaws as well as syphilis is a permanently negative Kahn or similar serum reaction. It is unnecessary to test the cerebrospinal fluid in yaws. I have treated thousands of cases of this disease, and in many studied the results by the Kahn test, an I have no doubt that adequate courses of N.A.B. with bismuth are necessary to effect a permanent cure.

In my experience it would be a grave mistake to ignore a one or two-plus Kahn in an African as suggested. If this is due to yaws, a small provocative dose of N.A.B. will increase the titre A cured case of yaws in childhood will not give a three- or four-plus Kahn in adult life unless there has been a reinfection with yaws o infection with syphilis, but I would point out that the number of West Africans having yaws in childhood or young adult life who receive adequate treatment to secure a cure as defined is at present I regret to say, very small—in fact, an infinitesimal proportion of actual cases.

Shortage of Medical Textbooks

Dr. R. D. GRAY (Chippenham) writes: The recent discussion in the House of Lords, and particularly the remarks of Lord Buck master, tempt me to report an example of maldistribution which may be of serious consequence if repeated up and down the country Some months ago, when the position with regard to *Gray' Anatomy* was so acute that one London medical student resorted to an advertisement in your columns, a new copy of the latest edition was in the front window of the Salisbury branch of a popular book seller and more were available within. While the shortage continues, it might reasonably be expected that publishers would assist by confining their deliveries to the recognized medical and scientific booksellers, and so avoid offering to the general public what the medical student cannot get.

Intestinal Obstruction by Gall-stone

Dr. ROBERT ANDERSON (Birmingham) writes: About 20 years ago I was called to see a woman of 75 who had been suffering from abdominal colic and vomiting for several days. There was not muc distension but there was visible peristalsis. On examination p.v. I found a hard mass behind the uterus and advised an operatio for relief. Her friends would not agree to it, but a few days afterwards they asked me to bring a surgeon. When he came he coul not find the mass I had found, but on opening the abdomen he pu his hand down into the pelvis and brought up a coil of small intestine with a hard mass in it. He incised the bowel and the mass was found to be a gall-stone fully an inch long and nearly as broad. The patient recovered. The surgeon was the late Albert Lucas, F.R.C.S.

"Predisposition" to War Neuroses

Dr. A. HARRIS writes from Wilmslow, Cheshire: With regard t Dr. Frederick Dillon's letter (April 21, p. 570), I would draw h attention to a paper by J. G. Sheps, "A Psychiatric Study o Successful Soldiers" (*J. Amer. med. Ass.*, 1944, **126**, 271).

Corrections

Dr. K. D. Salzmann wishes to correct a mistake in the lette published on May 26 (p. 748). The sentence should read ". . . Dr Read's teaching is that doctors must take more time and troubl in instructing and reassuring childbearing women" (not measuring

In the *Journal* of May 26 (p. 758) a note was published on "Di and Dental Health." The name of the author, Dr. A. Livingston should have been spelt without the final "e."

LONDON SATURDAY JUNE 9 1945

THE EFFECTS OF PROTEIN DIET ON INFECTIVE HEPATITIS

BY

E. M. DARMADY, M.B., M.R.C.P.

Squadron Leader, R.A.F.V.R.

(From an R.A.F. General Hospital)

The effects of diet on the course of various forms of jaundice have been the subject of some controversy. The purpose of this paper is to report on a series of 61 cases of infective hepatitis in men, 32 of which were treated with a high-protein diet with superadded vitamin B complex, and 29 by a classical low-fat diet in which the protein was not augmented.

Definition of Cases

Past experience of infective hepatitis has made it clear that the severity and the duration of the disease are extremely variable (Stocks, 1944; Higgins *et al.*, 1945). Recent claims have been made that the causal organism of infective hepatitis and N.A.B. and homologous serum jaundice are either similar or closely related. The fact that those diseases differ in their clinical course is best shown in Table I. The present series of 61 cases of infective hepatitis are compared with 54 cases of homologous serum jaundice resulting from the same icterogenic yellow fever vaccine. These have been arranged into four groups, depending upon the duration of the illness as originally suggested by Fox *et al.* (1942). The number of cases in each group has been expressed as a percentage of the total in each series.

TABLE I.—*Comparison with Serum Jaundice due to Yellow Fever Vaccine*

	Serum Y.F. Jaundice		Infective Hepatitis
	Fox *et al.*	Personal Series	
Days under treatment:	%	%	%
A: 21 or less	25	19	8
B: 22–49	40	39	86
C: 50–89	23	27	5
D: 89 or over and fatal cases	12	15	0
Cases in each series	759	54	61

It appears from the table that the majority of patients with infective hepatitis fall into Group B, whereas those of serum jaundice are spread over a longer period. This would suggest that the recovery rate of serum jaundice is of a scattered nature; in some the disease is transient, in others there is a greater tendency to relapse (10%). On the other hand, infective hepatitis appears to be largely self-limiting and recovery spontaneous.

In selecting cases for this experiment, therefore, the importance is stressed of using only those patients who gave a history of contact or in whom there was adequate epidemiological evidence of the disease. All cases which had been under arsenotherapy or had had yellow fever vaccine of an unknown batch number, or had had transfusions within 200 days of onset, were excluded. Five W.A.A.F. personnel were also treated under similar conditions, but, owing to paucity of numbers and possible sex differences in the rate of return to normal, these have not been included.

To exclude cases of Weil's disease a leucocyte count was made on entry, and in no case was a total of over 10,000 per c.mm. found. Infective mononucleosis was ruled out by differential counts and by the classical Paul-Bunnell reaction on selected cases. Only those who contracted the disease between Nov., 1943, and May, 1944, have been included in this series.

Criteria of Progress

During the course of treatment to assess progress four criteria were observed. (These were all based on the time taken to return to normal after admission to hospital.)

The first—the presence daily of bile in the urine—was tested by the iodine and foam test. The second—the excess of bilirubin in the serum—was assessed by the quantitative van den Bergh reaction as described by Harrison (1937), using the Lovibond disk. Normal was taken as being less than 0.6 mg. per 100 c.cm.; this test was made every fifth day initially, but later was carried out when the clinical signs suggested the icterus was minimal. The third criterion was the degree of parenchymatous liver degeneration as determined by the intravenous hippuric acid test of Quick (1939). The analysis of the urine, however, was carried out by the method of Weichselbaum and Probstein (1939). Two-hourly samples were used throughout, as these were considered to be more exact and sensitive. The fourth criterion was the time taken to return to duty.

Conditions of Experiment

It was decided to try the effects of foodstuffs readily available, supplementing these with vitamin B complex in the form of bakers' yeast. Two diets were arranged; the first, based on those of Patek and Post (1941) and Fleming and Snell (1942), contained 370 g. carbohydrate, 154 g. proteins, and 108 g. fats. Vitamin B complex was given as bakers' yeast, 30 g. daily by mouth. Parenteral liver (2 c.cm. of anahaemin) and thiamine hydrochloride 5 mg. were given twice weekly subcutaneously. Later the original diet was modified to a more fluid character for some patients in the initial stages. The second was a classical low-fat diet—320 g. carbohydrate, 70–90 g. proteins, 60 g. fats—and acted purely as a control. Vitamins were not supplied in excess of those already contained in the diet. Table II gives details of the diets used in the investigation.

Through the courtesy of the commanding officer a 40-bed ward was set aside for the treatment of infective hepatitis. Cases were admitted alternately, without prejudice, to the right and left sides of the ward. Those on the left side received the high-protein and vitamin B diet, and those on the right the control. Officers were accommodated in the side wards and were given the same diets as the airmen. The ward was never completely filled at any one time, so that this method of random allocation to the diet group presented no difficulties.

While in hospital patients were kept in bed until their liver function was found to be normal by the intravenous hippuric acid method. When the urine became bile-free they were allowed to go to a convalescent home, or, in the case of officers, on sick leave. Initially, during the period at a convalescent home those on the high-protein diets were returned to their normal airman's rations (approximately 100 g. of protein a day), and yeast was withheld. Later, the high-protein diet and yeast were continued during the entire treatment. When in the opinion of the medical officer in charge of the convalescent home evidence of clinical jaundice was minimal, the patient returned to the main hospital and the van den Bergh test was repeated.

TABLE II.—*Details of the Diets*

	Prescription (approximate)		
	High Protein (C., 370 g.; P., 154 g.; F., 108 g.)	Semi-fluid High Protein (C., 230 g.; P., 120 g.; F., 110 g.)	Low Fat (C., 320 g.; P., 70–90 g.; F., 60 g.)
Breakfast	90 g. prunes 30 g. cornflakes 15 g. sugar 180 g. milk 1 egg 60 g. bread 20 g. butter 15 g. sugar in tea 15 g. marmalade	180 g. milk 30 g. cornflakes 15 g. sugar 1 egg 60 g. bread 15 g. marmalade 20 g. butter	30 g. porridge 90 g. fruit 90 g. bread 90 g. marmalade 60 g. milk
9 a.m.	30 g. yeast 150 g. milk 15 g. sugar	30 g. yeast 150 g. milk 15 g. sugar	Lemonade 15 g. sugar
Dinner, 12 midday	90 g. meat 120 g. potatoes 90 g. vegetables 30 g. bread 20 g. butter 120 g. sweet 180 g. milk 15 g. sugar in coffee	90 g. mashed potatoes 15 g. butter 150 g. fish 90 g. vegetable purée 90 g. milk pudding	120 g. fish 120 g. potatoes 120 g. vegetables 90 g. milk pudding or fruit
2 p.m.	30 g. yeast 150 g. milk 15 g. sugar	30 g. yeast 150 g. milk 15 g. sugar	Lemonade 15 g. sugar
Tea, 4 p.m.	60 g. bread 15 g. butter 15 g. jam Green salad	60 g. bread 20 g. butter 15 g. jam	90 g. bread 60 g. jam 60 g. milk 8 g. butter
Supper	120 g. soup 90 g. meat 120 g. potatoes 90 g. vegetables 90 g. stewed fruit	120 g. soup 90 g. minced meat. 90 g. mashed potatoes 90 g. vegetable purée 15 g. butter	120 g. soup 90 g. meat 120 g. potatoes 90 g. milk pudding and stewed fruit
9 p.m.	180 g. milk	180 g. milk 15 g. ovaltine 15 g. sugar	180 g. milk 15 g. sugar

Comparison of Home and Oversea Cases

Of the 61 cases concerned in the experiment, 23 (8 of these were air-crew, 7 of whom were officers) had recently returned from North Africa within the prescribed incubation period of 30 days, and can be said to have contracted the disease away from this country. The remaining 38 (7 were air-crew, of whom 4 were officers—1 officer on ground duties was also included) had not left this country. To ensure that the disease of North Africa was no more severe than that contracted here, a comparative test was made. Table III shows the number of cases placed on each diet from home and oversea service. It is clear that precisely the same proportion of these two groups were on the experimental and the control diets.

TABLE III

	Experimental Diet	Control Diet	Total
Home cases	20 (52·6%)	18 (47·4%)	38
Oversea cases ..	12 (52·2%)	11 (47·8%)	23

This allows a comparison to be made (Table IV) between home and oversea cases without the possible effects of diet interfering. In order that these results should be comparable with those of other observers, the cases have been further subdivided. Those coming under treatment in hospital within one week of the initial symptoms are designated "early" and after this time "late."

TABLE IV.—*Comparison of Home and Oversea Cases. Mean Duration before Return to Normal in Days*

	Late Cases		Early Cases		Total Cases	
	Home	Oversea	Home	Oversea	Home	Oversea
Biliuria	15·0 (9)	12·4 (8)	11·4 (29)	11·8 (15)	12·3 (38)	12·0 (23)
Van den Bergh ..	26·6 (9)	20·4 (8)	24·3 (29)	24·4 (14)	24·8 (38)	22·9 (22)
Hippuric acid ..	16·3 (9)	11·6 (7)	12·8 (28)	12·5 (15)	13·6 (37)	12·2 (22)
Duration of treatment	34·0 (9)	25·8 (8)	32·0 (29)	30·5 (15)	32·5 (38)	28·8 (23)

The number of observations upon which the mean is based appears in brackets.

No significant difference is seen in the duration of any o the standards of fitness from either home or oversea sources It is therefore considered that the origin of the disease has n bearing on the effects of diets, and, in any case, since those o either diet include equal proportions of home and overse cases, there can be no error from this source.

The comparative figures for the diet groups are given i Table V.

TABLE V.—*Comparison of Diet Groups. Mean Duration and Standard Deviations in Days*

	Late Cases		Early Cases		All Cases	
	H.P. Diet	Control	H.P. Diet	Control	H.P. Diet	Control
Biliuria:						
Number of cases	10	7	22	22	32	29
Mean duration	13·0	14·9	12·5	10·6	12·6	11·7
S.D.			5·4	4·0	5·2	7·9
Van den Bergh:						
Number of cases	10	7	22	21	32	28
Mean duration	24·1	23·0	24·7	23·9	24·5	23·6
S.D.			9·1	10·2	8·0	12·7
Hippuric acid:						
Number of cases	10	6*	22	21	32	27
Mean duration	10·7	20·2	13·8	11·5	12·8	13·4
S.D.			7·1	9·6	6·8	15·7
Duration of treatment:						
Number of cases	10	7	22	22	32	29
Mean duration	28·0	33·1	33·1	29·9	31·5	30·7
S.D.			12·6	8·4	11·0	12·2

Owing to the small number of cases occurring in the late series the standar deviation has been omitted.

* This figure includes 1 case in which the liver function was subnormal through out hospitalization.

From Table V it is seen that cases coming under treatmen late are small in number and unevenly divided, whereas thos coming under treatment early are equally divided. In comparing results there does not appear to be any differenc between late and early groups. This is surprising, but may b explained by the fact that only those patients who did not sho any immediate response to treatment were transferred fro their station sick quarters. These cases tended to be mor severe than those in the early series.

Two cases placed on the high-protein diet relapsed. Thes were both air-crew, and both came under treatment early. Th first case—No. 20—relapsed while at the convalescent home Biliuria was absent and a normal liver function test was obtaine before entry to the convalescent home. This patient's secon period of biliuria and liver failure has not been included. Th second case—No. 8—was discharged from hospital bile-free the van den Bergh was within normal limits, and the liver function test was normal on discharge. Relapse occurred 11 day later. The second period of hospitalization of this case ha not been included, as the object of the experiment is to tes the time taken to return to duty.

Case 6, coming late under treatment in the control series, ha a prolonged course. Biliuria persisted for 80 days, and the live function test was still subnormal on discharge.

With so small an experience no significance can be attache to these few individual reactions. In general the evidence give by Table V is that there was no material difference at a between the two diet groups in any of the four characteristi measured.

Discussion

It is possible that the total numbers of cases may be considered to be too small for conclusions to be drawn from thes experiments; but it was felt that, since the epidemic perio occurs largely during the winter months, care must be taken include only those from any one winter period, in case of year variations in the severity or alterations in the type of th disease.

The importance of even distribution has been recognized allotting the diet, and statistical analysis has been undertake to ensure that the use of cases from different areas of infecti has not influenced the experiment. It would appear that disea of North Africa in no way differs from that in this countr As Clifford Wilson (1945) has recently stated, the patien stay in hospital is bound up with many proble other than their illness; for this reason other criteria have been taken to assess their progress.

The benefit of protein in this disease has largely been based upon the effects of diet in nutritional liver disorders. In the present series it is of interest to note that those on the experimental diet did not show any improvement over those in the control series. This is in striking contrast to the claims made by Beattie (1943–4), who has stated that with hepatitis it was possible to reduce the time spent in hospital by as much as 37% by dietetic measures alone. He further states that, roughly, the average stay in hospital is inversely proportional to the daily intake of protein. It is not clear to which type of hepatitis he refers, nor how much protein is given, but he quotes an average of 150 g. of protein a day in one series—the figure used here.

The active principle in preventing nutritional liver disorders has been traced to sulphur-containing amino-acids, of which methionine appears to be the foremost. It is not possible to determine the methionine content of the diets used in our series, but it is interesting to observe that Wilson *et al.* (1945) and Higgins *et al.* (1945), using oral methionine, were unable to find any statistical difference, using comparable criteria to assess progress.

Macrae *et al.* (1943) have demonstrated that the protein intake of the R.A.F. has exceeded the generally accepted standards of protein requirements. Whether the self-limitation of the disease as shown in Table I is due to the probable protein stores can only be a matter of conjecture. Himsworth and Glynn (1945) have pointed out that the case-mortality rate of the disease of allied pathology—post-inoculation jaundice—was 2.5% in the cases of Fox *et al.* (1942), whereas that in the cases of Findlay *et al.* (1944) it was 1.5%, the difference being considered to be due to the relatively poor nutrition of Fox's cases. This may suggest that the effect of protein is maximal as a protective but not as a restorative measure, and that, as protein deficiency is not found in the R.A.F., this may be the reason for the similarity of the two series. It is clear, however, that no harm arises as the result of the increased protein, and, in the meantime, a further experiment on similar lines is being undertaken with widely divergent protein intakes.

Summary

The progress of 61 cases of infective hepatitis in the R.A.F. is assessed; 32 were treated with high-protein diet with added vitamin B complex and liver extract; 29 were on a control diet. No response to this form of therapy is noted. Two cases relapsed following the high-protein vitamin B diet.

The recovery rate of a series of cases of jaundice due to icterogenic yellow fever vaccine is compared with a series of cases of infective hepatitis.

No difference has been found between the course of cases from North Africa and those from this country.

My thanks are due to Air Vice-Marshal Sir Harold Whittingham, K.C.B., for allowing me to publish this paper; to Dr. A. Bradford Hill (Consultant in Medical Statistics to the R.A.F.) for advice on the statistical analysis; to Group Capt. J. G. Russell and Group Capt. G. A. M. Knight, commanding officers of an R.A.F. hospital, for setting aside a ward for the treatment of these cases; to Wing Cmdrs. T. Macrae, O.B.E., and C. Hardwick, and Squad. Ldr. S. Yudkin, for criticism and advice; to Fl. Officer D. M. Forgan for supervision and preparation of the diets; to Sisters MacLeod and Fleet, of P.M.R.A.F.N.S., for the careful way in which the patients were supervised; and to the laboratory staff, who have met the extra work with zeal and enthusiasm.

CIVILIAN DYSPEPSIA

BY

F. AVERY JONES, M.D., M.R.C.P.

Physician in Charge of Dietetic Department, Central Middlesex County Hospital

AND

H. POLLAK, M.D.Prague

Physician, Central Middlesex County Hospital

Service reports leave no doubt that dyspepsia is an important medical problem of the war, and the purpose of this paper is to show that the same problem exists at home. The present series of cases covers two years—1943 and 1944—at a hospital which serves a large industrial and poor residential district in Greater London. All patients with dyspepsia were referred to the special dietetic out-patient department or to the dietetic wards under our care. Both the surgical and the medical complications of peptic ulcer were admitted to our department, and therefore a satisfactory perspective of the peptic ulcer problem was obtained. A small number of ulcer patients remained in other wards but were fed from the diet kitchen and have been added to our series; probably 98% of dyspepsia cases attending the hospital are included in our figures. The dietetic department has been working eight years, and therefore the figures represent an equilibrium which has been established with the district. A detailed history and examination were recorded in all patients, and are available for further analysis. Barium meal examinations were made in nearly every case, and gastroscopy was freely used in trying to achieve an accurate diagnosis. The clinical material is summarized in Table I. The series does not include about 200 patients referred from other hospitals for gastroscopy.

"X-ray negative" Dyspepsia

Of all new patients with gastric symptoms 59% have a peptic ulcer. The large group of non-ulcer dyspepsias (41%) will be the subject of a later report, and only a brief account of them will be given. First there was a small group of patients with obvious air-swallowing or nervous vomiting. Secondly, various physical causes may be finally diagnosed—e.g., chronic gastritis, gall-bladder disease, carcinoma ventriculi, early congestive heart failure, pulmonary tuberculosis, diaphragmatic hernia, or habitual purgation. In the majority of cases no definite diagnosis could be given, and they include all degrees of dyspepsia from slight occasional discomfort to regular remittent dyspepsia. At least half this group gave histories suggesting peptic ulcer, and sometimes a subacute gastric ulcer was found gastroscopically. We believe they are indeed peptic ulcer subjects, and correspond with the many patients with proved ulcers (especially duodenal) who give a history of having had a previous negative barium meal examination. Many of these dyspepsia cases seem to arise from the same factors that favour peptic ulcer—the rush and hurry of modern life, with its fatigue, worries, irregular meals, and nervous tension. Modern civilization provides good opportunities for the energetic and conscientious constantly to irritate their stomach. The intensity and duration of the stimuli may determine whether there is only irritability of the stomach or duodenum or a peptic ulcer is in process of formation.

It is worth noting that, although gall-bladder disease was constantly being looked for and many negative cholecystograms were being obtained, in only 23 (5 males and 18 females) out of 1,522 patients was there good evidence of cholecystitis or cholelithiasis; and as a cause of women coming to hospital with dyspepsia, duodenal ulcer (91 cases) was five times as common as gall-bladder diseases. These figures do not include the patients admitted to other wards with biliary colic or jaundice, but, even so, during 1944 the Medical Research Council Classification of Diseases Register (in-patients only) showed only 34, 20, and 4 admissions for the groups 545 (cholecystitis), 546 (cholelithiasis), and 547 (other gall-bladder diseases) respectively.

Table I.—*Summary of Clinical Material at the Central Middlesex County Hospital from Jan. 1, 1943, to Dec. 31, 1944*

In-patient admissions (general medical and surgical)	15,836		Excludes 2,582 mothers and 2,631 babies in the maternity department	
New patients attending consulting out-patient department (general medical and surgical)	16,074		Excludes ante- and post-natal, dental, electrical, *x*-ray, casualty, and V.D. departments. Many were probably admitted and are included in the first group	
New patients with gastric symptoms attending dietetic clinic as in-patient or out-patient, or both (but not counted twice)	1,522	G.U., 271 (F., 79) D.U., 681 (F., 91) Post-operative dyspepsias, 33 "*X*-ray-negative," 342 "*X*-ray-negative" haematemesis, 57 Duodenitis, 25 Pylorospasm, 28 Gall-bladder diseases, 23 Carcinoma ventriculi, 44 Gastritis, 21	The gastric ulcers include 42 acute gastric ulcers diagnosed gastroscopically and probably not visible radiologically. 58 "pyloric or juxtapyloric" ulcers are included with the duodenal ulcers	Gastric/duodenal ulcer ratio 1 : 2·5
Admissions with frank haematemesis and/or melaena	220	G.U., 56 (F., 23) D.U., 67 (F., 14) Post-operative, 15 (F., 3) "*X*-ray-negative," 57 Miscellaneous, 25	The gastric ulcers include 15 ulcers demonstrated gastroscopically but not visible when *x*-rayed during convalescence	Gastric/duodenal ulcer ratio 1 : 1·2
Admissions with perforations	90	G.U., 11 (F., 1) D.U., 77 (F., 7) Jejunal ulcer, 2		Gastric/duodenal ulcer ratio 1 : 7
Deaths attributable to peptic ulcer	27	G.U., 15 D.U., 11 J.U., 1	Haemorrhage, 11 deaths Perforation, 10 deaths (3 not operated on) After elective surgery for peptic ulcer, 6 deaths (116 partial gastrectomies and 16 gastro-enterostomies)	Gastric/duodenal ulcer ratio 1 : 0·73

Peptic ulcer was diagnosed in 952 patients.

Table II.—*Peptic Ulcer Cases*

	M.	F.	Total	F./M. Ratio
Acute gastric ulcer (gastroscopic) ..	21	21	42	1 : 1
Chronic gastric ulcer (lesser curvature or adjacent anterior or posterior walls)	171	58	229	1 : 3
Pyloric ulcer	46	12	58	1 : 4
Duodenal ulcer	544	79	623	1 : 6
Total	782	170	952	1 : 4·7

Age and Sex Incidence

The accompanying Chart shows the maximum incidence for gastric ulcer between 40 and 60, but duodenal ulcer has an earlier peak at 35 to 39. The pyloric ulcer curve corresponds more closely with the gastric ulcer than with the duodenal ulcer curve, but a possible fallacy may be that scarring from long-standing duodenal ulcer may cause deformity of the pyloric canal.

Apart from the rapidly healing acute ulcers, in which the sex ratio is equal, there is a big preponderance of men, and it is interesting to note the different sex ratios. As duodenal ulcer has a different sex and age incidence from gastric ulcer it is possible that different factors are involved in their causation. There are big variations in the proportion of gastric and duodenal ulcer in various series from different parts of the country and from different sections of the community. If there are varying aetiological factors between gastric and duodenal ulcer a clue might be found where there are significant differences.

Relative Incidence of Gastric and Duodenal Ulcer

There are six possible fallacies in comparing published figures. First, the civilian series refer without exception to patients admitted to hospital or nursing homes. It is fair to say there is a bias towards admitting gastric rather than duodenal ulcer cases because a large lesser-curve ulcer is more impressive than a deformed duodenal cap, and the patient often looks more ill. Further, there may be a suspicion of malignancy with a gastric ulcer. One of us (F. A. J.), working at St. Bartholomew's Hospital before the war, can confirm the operation of the bias. The pressure on beds did not allow uncomplicated ulcers to be admitted, and the majority of duodenal ulcer patients were returned to their doctor after the *x*-ray diagnosis had been established. In 1936 the G.U./D.U. ratio of in-patients was 1 : 0.79, but an examination of the *x*-ray department reports in the same year showed a G.U./D.U. ratio of 1 : 2.2. Secondly, it is necessary to know how often pyloric or pre-pyloric ulcers are diagnosed and whether they are included with the gastric or the duodenal ulcers. There is good reason for following Illingworth *et al.* (1944) and including them with the duodenal ulcers, for at operation it may be very difficult to decide whether the ulcer is pyloric or duodenal, and it is our experience that the radiological diagnosis of pyloric ulcer is not always confirmed at operation and the ulcer may be duodenal; and, further, a pre-pyloric ulcer is extremely rare gastroscopically. Thirdly, it is fallacious to argue from the proportion of ulcers which bleed, perforate, or cause death, as can be seen by the variation in ratios in this series of consecutive cases attending one hospital (Table I). Fourthly, the social status is apparently significant, for death-rate studies show that

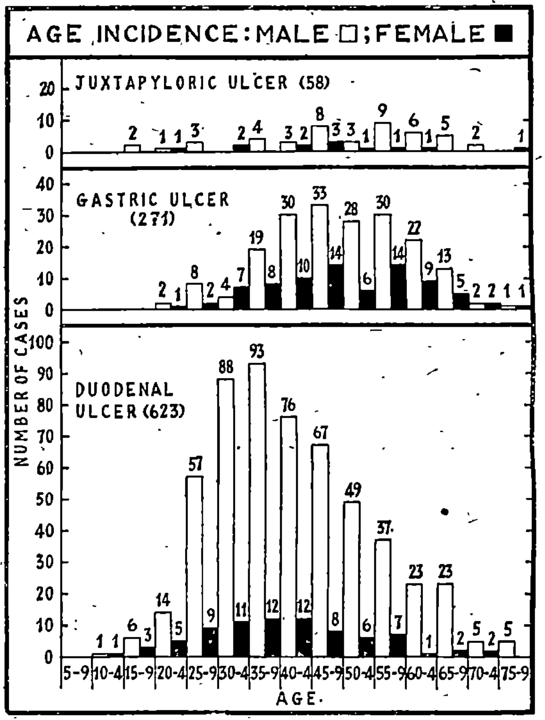

Chart showing the age and sex incidence in a series of 952 cases of peptic ulcer at under 65 gastric ulcer is more lethal in the poor and that duodenal ulcer causes more deaths in the wealthy than in the poor (Morris and Titmuss, 1944). Fifthly, the age incidence of different series is most important, because the age peak for duodenal ulcer is apparently earlier than for gastric ulcer (see Chart). Taking only males under 45, the G.U./D.U. ratio changes from 1 : 2.5 for the whole series to 1 : 5.5 ! The sixth fallacy may be the inclusion of "*x*-ray-negative" gastric ulcers diagnosed gastroscopically. In many of the previous series gastroscopy has not been performed, and the exclusion of such cases from our series would alter the G.U./D.U. ratio from 1 : 2.5 to 1 : 3.0.

Taking these points into consideration, it may be profitable to review the figures given for London, elsewhere in the country, from the Services, and for private patients.

TABLE III.—*London Series*

Source	No.	Year	G.U./D.U. Ratio
Registrar-General (Tidy, 1944)	— —	1921 1928	1 : 0.36 1 : 0·42
Admissions to L.C.C. Hospitals (Daley, 1942)	15,443	1933–8	1 : 0·62
In-patients at London Hospital (Souttar, 1927)	1,275	1923–5	1 : 1·0
Admissions to St. Thomas's Hospital (Tidy, 1944)	870 986 862	1926–7 1930–3 1934–7	1 : 0·66 1 : 0·45 1 : 0·40
Admissions to St. Bart's	335	1936	1 : 0·79
Sample of *X*-ray dept.'s barium meal reports at St. Bart's	80	1936	1 : 2·2
The present series	952	1943–4	1 : 2·5

Our conclusion that duodenal ulcer is 2½ times as common as gastric ulcer is the complete reversal of previous series, and we believe the difference is due to the inclusion of out-patients in our series. This view is supported by the difference between the G.U./D.U. ratio at St. Bartholomew's Hospital in 1936 for in-patients (1 : 0.79) and the *x*-ray department figures for in-patients and out-patients (1 : 2.2)—suggesting that the majority of duodenal ulcer cases were not admitted to the wards. The Registrar-General's ratio is probably fallacious, for a chronic gastric ulcer is more lethal than a duodenal ulcer should bleeding or perforation occur.

TABLE IV.—*Service Series*

	No. with Dyspepsia	G.U./D.U. Ratio*	% Ulcer	
Army:				
Morris (1940) ..	500	1 : 8·7	42·8	D.U. include 10%† juxtapyloric ulcers
Brockbank (1942) ..	931	1 : 6·5	41·5	D.U. include 6·3%† juxtapyloric ulcers
Spillane (1941) ..	200	1 : 4·5	32	No mention of pyloric ulcers
Graham and Kerr (1941)	246	1 : 5·9	64	,, ,,
Hill (1943)	197	1 : 4·7	34·6	D.U. include 4·5%† pyloric ulcers
Tidy (1941) ..	2,500	1 : 4·4	51·9	D.U. include 8% pyloric ulcers
Hinds Howell (1942)	1,422	1 : 4·6	51	D.U. include 5%† pyloric ulcers
Payne and Newman (1940)	287	1 : 4·2	78	No mention of pyloric ulcer
Navy:				
Wade (1942) ..	1,063	1 : 6·0	45	,, ,,
Allison and Thomas (1941)	100	1 : 5·7	45	
R.A.F.:				
Rook (1943) ..	194	1 : 4·0		
Present series (1943–4):				
Males under 45 ..	610	1 : 5·5	66	

* Where possible, calculated to include pyloric ulcers with duodenal ulcers.
† These percentages refer to the total series.

Where possible, the figures given include the pyloric ulcers with the duodenal ulcers ; this can be a significant factor; for if included with the gastric ulcers Hinds Howell's series gives a ratio of 1 : 2.5 instead of 1 : 4.6. The overwhelming preponderance of duodenal ulcer is seen in all the series, and it seems to correspond to the ratio 1 : 5.5 obtained from our civilian series by taking only males under 45.

Nicol (1941) suggests there may be significant variations in different parts of the country, and gives the following figures :

TABLE V.—*Geographical Variations*

	G.U./D.U. Ratio		G.U./D.U. Ratio
Glasgow (Young, 1927) ..	1 : 6·4	Leeds (Flint, 1927) ..	1 : 2·8
Aberdeen (Nicol, 1941) ..	1 : 6·8	London (Souttar, 1927) ..	1 : 1·0
Edinburgh (Wilkie, 1927)	1 : 6·1		

Nicol doubted the validity of the London figure, and his suggestion that more duodenal ulcers are treated at home seems to be correct, but there is still a gross discrepancy with the Scottish figures. Whether this may be due to an absolute increase in duodenal ulcer or whether gastric ulcers are less frequent in Aberdeen remains to be studied. Table VI gives available figures for private cases.

TABLE VI.—*Private Cases*

	No.	G.U./D.U. Ratio
Aberdeen (Nicol, 1941)	229	.... 1 : 4·5
London (Ryle, 1932)	261	.... 1 : 4·0
New Lodge Clinic, London (Barford, 1928)	166	.... 1 : 4·3

There is probably little selection with private cases, for all who are seen in consulting-rooms or nursing homes are likely to be included. Even if the pyloric ulcers are included with the gastric ulcers there is a greater incidence of duodenal ulcer than in our own series, and duodenal ulcer may be more common in private than in hospital practice.

Ratio of Fatal Cases to New Patients

During the two years 1943–4 there were 1,522 new patients with gastric symptoms ; 952 of these had proved peptic ulcer, and 27 died from peptic ulcer—i.e., there were 35 new patients for every death from ulcer. The ratio is open to criticism, but the possible fallacies may in part cancel themselves. The number of ulcer cases does not take into account the patients diagnosed as "*x*-ray-negative" dyspepsias with an ulcer-like history, and it does not include the "*x*-ray-negative" haematemesis and melaena or patients with pylorospasm. The majority of such patients are probably candidates for peptic ulcer if ulcers are not already present.

Our numbers are too small to allow more than a rough calculation, but they help to provide an estimate for the ulcer population in England and Wales. First, between 1929 and 1938 there were 43,200 deaths from peptic ulcer, and therefore 43,200×35=1,512,000 people may have developed ulcers during that time. Secondly, comparing the age incidence of our new patients and our deaths, and applying the ratio in each age group to the national figures, an estimate can be made of the number of ulcers beginning in one year (Table VII).

TABLE VII.—*Estimate of Number of Ulcers beginning in One Year (Males only)*

Age Group	Cases	Deaths	Ratio	National Deaths (1938)	National Cases
–15	1	0	—	0	0
15–25	25	0	160 ×	54 =	9,000*
25–35	160	1	160 ×	170 =	27,000
35–45	225	1	225 ×	488 =	110,000
45–55	188	10	19 ×	882 =	17,000
55–65	127	5	25 ×	1,063 =	26,000
65–75	50	4	12 ×	644 =	8,000
75+	6	1	6 ×	251 =	1,500
Total ..	782	22		3,552	198,500

* Assumed age 25–35 ratio.

This would suggest that nearly 200,000 men develop peptic ulcer each year. The mortality of patients treated in a specialized gastro-intestinal clinic is likely to be lower than in the country as a whole. This may be offset by the probability that most gravely ill patients are sent to hospital, whereas many with mild peptic ulcer symptoms are treated by their doctor and not referred to us.

Thirdly, the post-mortem incidence of active or healed ulcer in the stomach or duodenum has been given as 10.25% of all necropsies in a general hospital (Hurst and Stewart, 1929).

Mr. R. M. Titmuss has kindly assisted us with these calculations, and considers we are justified in giving a rough estimate that the number of living people in England and Wales who have suffered from peptic ulcer is around 1,500,000 and may even be higher. We do not wish to stress these figures except to indicate that peptic ulcer seems to be an appreciable problem in this country.

Peptic Ulcer: A Modern Industrial Problem

Unfortunately many cases of peptic ulcer relapse, and the majority of those who have had ulcers have to follow simple rules to avoid further symptoms—e.g., regular meals with balanced diet, avoidance of common indigestible foods, avoidance of undue fatigue, and maintenance of a calm philosophical outlook on life. It is a problem which mainly confronts men during their working life and often when at their prime. Although peptic ulcer does not cause heavy loss of life (little more than 1% of non-violent deaths) it results in much suffering and incapacity for work. The ulcer subject has "guts" even if they are weak ones, and he does not give in easily. The man with a duodenal ulcer is usually of special value to industry, for he is over-conscientious, with plenty of drive and a sense of good standards of work.

The magnitude of the problem demands further study of those factors in modern industrial life which favour peptic ulcer.

Summary

An analysis in given of all patients with digestive trouble coming to a large general hospital in Greater London. Of 1,522 patients, 952 were found to have peptic ulcer.

The ratio of women to men with peptic ulcer was 1 : 4.7.

The ratio of gastric to duodenal ulcer was 1 : 2.5. This is higher than in previous London series.

The ratios of previous series are considered and possible causes for discrepancies discussed. An important factor is the exclusion of out-patients in most series, for patients with duodenal ulcer probably have less chance of hospital admission than those with gastric ulcer.

The ratio of gastric and duodenal ulcer in Service series is found to be equivalent to the figure for males under 45 in the present civilian series.

Calculations suggest there are about 1,500,000 living people in England and Wales who have suffered from peptic ulcer.

Thanks are due to Miss C. F. Harris, our dietitian, who has kept a careful record of all in-patient and out-patient diagnoses. We are also grateful to Mr. R. M. Titmuss for statistical advice.

Increased standard rates of pay and improved conditions of service for mental nurses in Scotland are among the recommendations by the Scottish Nurses' Salaries Committee to the Secretary of State, who commends them for adoption by hospitals in a circular issued by the Department of Health for Scotland. The Taylor Committee has been dealing during the last three years with nurses' salaries and has still to submit its complete report, but puts forward to the Secretary of State a summary of the points on which agreement has been reached up to date. The present recommendations will apply from April 1, 1945. The scales awarded are broadly similar to those recommended last year by the Rushcliffe Committee for mental nurses in England and Wales.

NUTRITIONAL MACROCYTIC ANAEMIA AND THE ANIMAL PROTEIN OF DIET

BY

GEOFFREY F. TAYLOR, M.R.C.P.

Lieut.-Col., I.A.M.C.

AND

P. N. CHHUTTANI, M.D., D.T.M.

Major, I.A.M.C.

The incidence of anaemia, especially of nutritional macrocytic anaemia, in relation to the animal protein content of the diet is of interest in countries such as India, where most of the population live on barely adequate or frankly inadequate diets. During war and post-war periods, when nutritional anaemias are probably more widespread, the subject becomes of world-wide importance.

The study of the incidence, type, and severity of cases of anaemia in relation to the diets of a population affords some evidence of the inadequacy of such diets. This note is based on 50 consecutive unselected cases of anaemia seen between May 1 and Sept. 15, 1944, studied from this point of view. They occurred among a population of adult male Indians (17,000 meat-eaters and 1,188 vegetarians), all the sick of which were admitted into one hospital. The men had been on known rations for over two years. The men and their quarters were medically inspected regularly. The locality was a desert and the climate was extremely hot in summer. The hospital admission rate was the low one of 1.5 per 1,000 per day. There was practically no fresh malaria and the dysentery rate was very low. All cases with red blood counts of under four million cells per c.mm. or corresponding haemoglobin of under 11.6 g. were investigated, with the exception of cases admitted for obvious pulmonary tuberculosis. This arbitrary standard was adopted to exclude borderline cases.

The following normal ranges for absolute values, suggested for general use in India by Napier and Das Gupta (1942), were adopted for analysis of this series: mean corpuscular haemoglobin (M.C.H.) of 24 to 33 micromicrograms ($\gamma\gamma$), mean corpuscular haemoglobin concentration (M.C.H.C.) of 30 to 35%, and mean corpuscular volume (M.C.V.) of 80 to 100 cubic microns (c.μ).

Examinations were carried out on oxalated venous blood. The standardized Sahli haemoglobinometer was used. Stool and urine examinations, test-meal, sedimentation rate, Kahn test, and skiagrams of the chest were carried out, in addition to a full clinical examination, in all cases. The first blood examination figures, after admission, and the results of other investigations, are shown in Table I.

All 50 cases, except one, had complicating factors (Table II). An analysis of the 50 cases according to age, occupation, race, and living conditions failed to bring out any differences; but it was found that 27 of them were lifelong vegetarians, 2 were temporary vegetarians, and 21 meat-eaters. The vegetarians had never taken meat or eggs. The vegetarians and meat-eaters were fed from the same kitchens. They were equally exposed to malaria, hookworm, and other diseases. No difference in general body development was seen in the two groups. The two temporary vegetarians suffered from dyspepsia and undulant fever. The dyspeptic patient had omitted meat from his diet for six months. The undulant fever case had lived on a hospital milk diet without meat or eggs for two months.

It was possible to check with some accuracy what was eaten. The daily rations were: 18 oz. of atta (wheat flour) or rice, 2½ oz. of dhal (pulses), 3¼ oz. of ghee (clarified butter or vegetable oil), 2/3 oz. of condiments, 2 oz. of onions, 2 oz. of potatoes, 4 oz. of fresh vegetables, and 6 oz. of fresh mutton with bone, for five days in a week. Leafy vegetables were issued for only a few months of the year. The vitamin A content of the diet was also known to be low. In lieu of fresh meat vegetarians were allowed 4½ oz. of tinned milk three days a week, and 3/4 oz. of ghee and 3 oz. of atta or rice for two days a week. This amounted in practice to one tin of unsweetened milk containing 13 fluid oz., equivalent to 26 oz. of fresh milk, each week. But of 27 vegetarians with anaemia only 11 had received milk in lieu of meat. No one had bought any extra milk from canteens or elsewhere. The meat ration of 6 oz. of fresh mutton with bone for five days a week amounted to 4 oz. without bone. This was checked in local carcasses. Therefore, 20 oz. of fresh mutton without bone weekly was the main difference in the diets of vegetarians and meat-eaters, although 11 vegetarians had been drinking one tin of milk weekly. Excluding milk and meat rations, the diet contained over 3,000 calories and over 80 g. of vegetable protein. The diet is emphasized because the anaemia, in its type and severity, was closely and regularly related to the diet consumed.

Classification

Haematologically, the cases grouped themselves as follows: Normocytic-orthochromic, 2; normocytic-hypochromic, 15; microcytic-hypochromic, 3; macrocytic-hyperchromic, 25; macrocytic-orthochromic, 4; and macrocytic-hypochromic, 1. It was found that (*a*) 17 out of the 20 normo-microcytic group were meat-eaters, and (*b*) 26 out of 30 of the macrocytic group were vegetarians. The remaining 4 were meat-eaters and cases of sprue.

Aetiologically, as a low M.C.H.C. is accepted as indicating iron deficiency, and a high M.C.V. or macrocytosis as usually indicating a haemopoietic-principle (or principles) deficiency, the cases can be classified as: (i) Iron-deficient normo-microcytic cases consisting of 17 meat-eaters and 3 vegetarians. Sixteen were infested with hookworm, three had malaria, and one was a case of idiopathic hypochromic anaemia. (ii) Haemopoietic-principle deficiency macrocytic cases, consisting of 24 cases of nutritional macrocytic anaemia (all vegetarians), 5 cases of sprue, and 1 case associated with undulant fever. Nine of the nutritional macrocytic cases were "dimorphic" (see later). Thus there were two main groups—17 meat-eaters who had iron-deficiency (low M.C.H.C.) hypochromic anaemia, and 24 vegetarians with nutritional macrocytic anaemia. These significant facts are examined later in relation to the numbers of the population from which the cases were admitted.

Before this investigation there was a clinical impression that severe anaemia was associated with vegetarianism in this Indian population. To test this impression the cases were analysed according to severity. Severe anaemia was arbitrarily defined as one with a red cell count of two millions or below, or a haemoglobin of 5.8 g. (which is comparative to this R.B.C. level) or below. It was found that, whereas there was only one case (No. 10) of severe anaemia in the iron-deficiency group of 17 meat-eaters, there were 11 cases of severe anaemia in the 24 vegetarians with nutritional macrocytic anaemia. Three of the five sprue cases had also a severe anaemia. The only severe anaemia seen among the meat-eaters (excluding sprue cases) was not clinically serious. But the majority of the severe cases among the vegetarians were obviously seriously ill on admission to hospital.

Incidence

In view of the contrast in type and severity of anaemia shown by the vegetarian and the meat-eating patients in this series, the incidence was examined according to diet. It was found that in 4½ months 17 cases of anaemia came from the group of 17,000 meat-eaters and 26 from the 1,188 lifelong vegetarians—a rate of 2.6 per 1,000 per year for meat-eaters and 58.5 per 1,000 per year for vegetarians. Anaemia associated with sprue and undulant fever was excluded from the incidence analysis for the reason that the anaemia occurred during the course of another serious illness. The 24 cases of nutritional macrocytic anaemia came from the vegetarians—a rate of 54.1 per 1,000 per year. Not a single case came from the meat-eaters. Of the 20 cases of iron-deficiency anaemia 17 came from the meat-eaters and the remaining 3 from the vegetarians. Nine of the nutritional macrocytic cases also had iron deficiency (low M.C.H.C.), so that the incidence of iron deficiency was 10 times greater in vegetarians than in meat-eaters.

Severe anaemia as already defined occurred at a rate of 24.7 per 1,000 per year in the vegetarian group and 0.16 per 1,000 in the meat-eaters.

It would be of interest to compare these results with the incidence in areas where malaria and dysentery are rife.

Some Clinical and Haematological Features

1. The iron-deficiency group of 20 cases was mainly a mild normocytic-microcytic hypochromic anaemia. The red cell counts in the group varied between 3,000,000 and 5,500,000 (Hb only 10.5 g. in the latter case). The haemoglobin varied between 4.96 and 10.9 g. The 4 cases in this group which were not infested with hookworms were associated with malaria in three instances, and the fourth was an idiopathic hypochromic anaemia.

2. The 30 macrocytic anaemias were classified into 24 cases of nutritional macrocytic anaemia, 5 cases caused by sprue, and 1 case associated with undulant fever. In the 24 nutritional macrocytic cases the blood picture, as shown in Table I, was varied. The lowest red cell count was 1,080,000 and the lowest haemoglobin 4.46 g. Clinically, out of 11 severe cases 7 were seriously ill and were confined to bed. Others, though suffering from advanced anaemia, had few complaints. It was of

interest to note that men with red cell counts below two millions were doing full duties before admission. Though every one of these 24 cases had a complicating factor, which was irregularly distributed, the incidence of such factors was not higher than in the remaining 26 cases, except that bacillary dysentery or its history was present in 9 cases and not in the anaemia of other groups. But each case occurred in a vegetarian, and, what is more, not a single meat-eater of the 17,000 had developed this type of anaemia. Vegetarianism was thus thought to be the principal cause of nutritional macrocytic anaemia in this series. It is not, however, the purpose of this note to discuss what is present in the meat ration which prevents the occurrence of macrocytic anaemia.

One case showed how quickly a severe nutritional macrocytic anaemia may develop. A champion wrestler—a vegetarian—had had excellent rations, with four extra tins of milk weekly, and plentiful fruit and vegetables, as he lived in a fertile part of the country. He was transferred to the desert, where his ration contained little or no fruit and vegetables, and no milk. After three months of this diet he developed a severe macrocytic anaemia with a red cell count of 1,250,000 and Hb of 4.9 g.

In the 5 cases of sprue anaemia there was nothing of particular note.

The patient with severe undulant fever developed macrocytic anaemia after two months in hospital. In health he was a meat-eater, but in hospital was given a milk diet without eggs. There was no clinical anaemia on admission, but after two months' fever he looked very pale, which led to a full blood investigation, with the following results: R.B.C., 2,100,000; Hb, 6.72 g.; M.C.H., 31.5 $\gamma\gamma$; M.C.H.C., 26.28%; M.C.V., 119.0 c.μ. The sternal marrow differential count showed 7.75% megaloblasts, 14% erythroblasts, 27% macroblasts, and 18% normoblasts. No other anaemia-producing factors were present. The blood picture in this case was of interest because undulant fever usually produces a microcytic anaemia, the macrocytic form being rare. The anaemia usually is not severe. Strong (1942) says: "The lowest recorded count by Basset-Smith was 2,500,000, and by Kern 2,800,000."

3. That 9 of these 24 macrocytic cases had an M.C.H.C. below 30% was of interest. Four were infested with hookworms. Two had achlorhydria, but free acid returned as anaemia disappeared. In the remaining three the iron deficiency appeared to be purely dietetic in origin. These 9 cases were similar to the "dimorphic" group recently emphasized by Trowell.

4. Koilonychia occurred in 7 cases (Table III). There was a low M.C.H.C. in all except one. Five cases had hookworm infestation. In one of these there was achlorhydria. The case with a normal M.C.H.C. (30.5%) had an M.C.V. of 127 c.μ.

5. Test meals gave the following abnormal results. Achlorhydria was present in 7 nutritional macrocytic anaemias and 5 iron-deficiency anaemias on the first examination. Acid was later found in four of the former group and two of the latter. Histamine was not available.

6. The results of the examination of the lips, buccal mucous membrane, tongue, and eyes have been tabulated. Cheilitis and angular stomatitis were common, but exact records were not kept in the earlier cases. Sublingual glossitis was a condition in which the under surface and sides of the tongue were very red and tender, and, in some, large red papules were present.

TABLE III.—*Findings in Mouth, Eyes, and Nails*

Disease	Meat-eaters	Vegetarians	Temporary Vegetarians	Sprue
Generalized glossitis	—	8	—	5
Geographical tongue	2	4	—	—
Sublingual glossitis	4	4	—	—
Enlarged numerous fungiform papillae	11	16	—	2
Koilonychia	5	2	—	—
Bitot's spots (xerophthalmia) ..	—	2	—	—

Conclusions

A full blood investigation of 50 consecutive cases of anaemia in Indian men in an extreme desert climate, where there was a low sickness rate (about 1.5 per 1,000 per day), showed that the admission rate to hospital for anaemia per 1,000 of population among vegetarians was 22 times greater than among meat-eaters. The incidence of severe anaemia was very much greater in vegetarians than in meat-eaters in this series.

The anaemia differed in type and severity in the two groups, being mainly macrocytic in the vegetarians (nutritional or tropical macrocytic anaemia) and hypochromic and either normocytic or slightly microcytic in the meat-eating group. No case of nutritional macrocytic anaemia was seen in a meat-eater.

In all cases except one a complicating factor was found, hookworm and malaria being most frequent.

The difference in the habits of the two groups, which were otherwise alike, was that social customs prevented the vegetarian group from eating the weekly ration of 20 oz. of fresh mutton in the meat-eaters' ration. The absence of this meat appeared to be the cause of macrocytosis and severity and frequency of anaemia in the vegetarian group. The rations contained over 3,000 calories and over 80 g. of vegetable protein. Riboflavin and vitamin A were known to be low.

It will be of interest to compare these results with findings when the stress of severe frequent malarial infection and dysentery is great.

One case showed that a severe macrocytic anaemia may develop within three months if milk, fresh fruit, and vegetables are much reduced in a vegetarian diet. Another case in which severe macrocytic anaemia developed during a prolonged fever (undulant fever) showed the need of liver and iron in the diet in cases of chronic illness.

Summary

The incidence, type, and severity of anaemia in an Indian adult male population of about 18,000 were shown to depend on the meat content of the diet. Nutritional macrocytic anaemia occurred only in vegetarians in a series of 50 cases.

THE DIAGNOSIS OF DOUBTFULLY PENETRATING ABDOMINAL WOUNDS

A LESSER OPERATIVE PROCEDURE

BY

CHARLES DONALD, O.B.E., Ch.M., F.R.C.S.
Brigadier, Army Medical Service

A diagnostic procedure for doubtfully penetrating abdominal wounds, introduced by me in the Desert Campaign and thereafter often referred to among field surgeons as my test, has recently (Rogers, 1944) been designated, not unkindly but with some lack of euphony, "Donald's explorotomy." Rogers mentions the test as if it were generally known, and does not elaborate it. Lest other references should appear I feel i advisable to put a description on record; otherwise the implications and limitations may not be understood. The circumstances attending its origin are not without interest.

In the casualty clearing stations behind El Alamein there wa great congestion of casualties for the first week or so of the battle. Only first priority cases could be operated upon; al else had to travel on to the base hospitals, not far away i distance but a fair way in time. The first-priority cases wer numerous enough to overwork the surgeons, and amon abdominal cases there had to be a discrimination as to wh were worth operating upon and who were not, to an exten that I have not seen repeated.

Most penetrating wounds of the abdomen are easil diagnosed. With experience on the part of the surgeon th proportion of doubtful penetrations, usually with wounds o entrance at a distance, becomes less. But till that experienc is gained, and after then in lesser degree, there are cases i which doubt remains and precious hours are allowed to pas in waiting for more signs. The alternative is an explorator laparotomy. When severe casualties are waiting their turn i large numbers, as at El Alamein, it is galling to do a negati laparotomy of the usual searching kind, and under field conditions this wastes more than a good hour of time and a great deal of energy.

It soon became apparent to me that no missile ever entered the peritoneal cavity without, by the time the patient reached the surgeon, there being some blood, little or much, in the pelvis. Such did not necessarily imply that a viscus had been injured, only that the abdominal wall had been completely pierced, with some bleeding from it into the general peritoneal cavity. Even without visceral injury there could be a large collection of blood if a particular vessel in the parietal wall had been hit; there was always some. From civil practice one recalls how irritatingly a stab incision through the abdominal wall can bleed until it is tautened on the drainage-tube. The absence of any blood in the pelvis, conversely, meant that the parietal wall had not been pierced.

The Method.—A time-saving, and life-saving, procedure in doubtful cases, based on this fact, seemed justifiable in the conditions then existing. Instead of the usual large laparotomy, turning over of the gut, and palpation of other viscera, a small 1½-in. exploratory incision, halfway between umbilicus and pubis, was made. Through this a swab on a long holder was passed to the pouch of Douglas. If no blood was found on the swab the incision was closed. If the swab was blood-stained the wound was extended into a proper laparotomy, which might or might not reveal visceral injury as well. The small incision was made through the rectus muscle, as any extension necessary then produced what was regarded generally as the quickest and best of abdominal incisions in abdominal injuries—the vertical rectus-splitting. The procedure does not take more than 20 minutes, time for induction of anaesthesia included.

The value of a test depends in great measure on its proper performance and interpretation. It is necessary, for instance, to make sure that the swab on the holder is not soiled on its passage through the small exploratory hole. Again, a purely retroperitoneal injury, perhaps necessitating laparotomy, will of course not give a positive result, but the position of the wound, the signs, and often the odour from it, will not lead one into the performance of the test under these conditions.

While I did not advise the test to be done save under exceptionally busy circumstances, where the greatest good of the greatest number was the prime consideration, it would now be of interest to know of any other experiences in the matter. Personally I have not heard of an instance where a negative finding on the swab did not mean one could shut up the small incision with confidence. While the same thought of the underlying principle must have entered other surgeons' minds, I have found no note of it in the literature, and experienced surgeons of the last war tell me it was not a practice known to them.

Rogers, in the article above referred to, indicates the value of the test in those few cases in which the signs leave doubt as to the advisability of operating, and (*a*) the amount of shock seems out of proportion to the external wounds, (*b*) the haemoglobin and red cell count are lower than normal in early cases or the white cell count higher than normal in late cases, and (*c*) the failure of the patient's condition to improve in a reasonable time.

While I agree with these indications I think they suggest that the doubt arises only in cases of the relatively ill. I would add the occasional case in which the patient is relatively well but his signs are equivocal, and something—call it clinical sense or what you will—leaves the examiner unhappy as to delaying for what may be precious hours. Writers on the subject of abdominal wounds usually record a proportion of negative laparotomies. If, especially in shocked patients, the exploration can be cut down to what is described above, then lives as well as time may be saved.

REFERENCE

Rogers, L. S. (1944). *Austral. New Zeal. J. Surg.*, 14, 1, 37.

J. McConnell (*Amer. J. med. Sci.*, 1945, 209, 41) describes an outbreak of epidemic pleurodynia affecting young women in a nurses' training school. The source of the epidemic was not determined. Signs and symptoms referable to the central nervous system were usually present. In three patients the symptoms resembled those of meningo-encephalitis. Attempts to reproduce the disease in animals failed.

CASE-FATALITY RATES OF GAS GANGRENE IN RELATION TO TREATMENT*

BY

M. G. MACFARLANE, Ph.D.

(Lister Institute of Preventive Medicine, London)

The War Wounds Committee of the Medical Research Council recommended in 1940 a combination of measures for the treatment of gas gangrene—the use of surgery and bacteriostatic drugs to control the infection and the use of polyvalent antitoxin to alleviate the toxaemia. At this time the therapeutic value of antitoxin in clinical gas gangrene had not been assessed. It was shown later, by analysis of the case reports on Army Form I 1241 (Macfarlane, 1943), that the fatality rate was significantly lower among patients who received prompt treatment with antitoxin in addition to surgical treatment; even among those who underwent amputation of the affected limb within six hours of diagnosis the beneficial effect of antitoxin was demonstrable. It seemed clear that, in general, the combined use of surgery and antitoxin was more effective in saving life than either of these measures alone, but it was pointed out that patients in whom the gas gangrene involved the thigh or buttock region showed a poorer response to treatment than those in whom the lower leg or arm was affected. This was thought to be due to the difficulty of controlling the infection in a region with a relatively poor collateral circulation and in which surgical elimination of the infection might be difficult or impossible.

In a later memorandum (M.R.C. War Memorandum No. 2, revised edition, 1943) it was recommended that the initial dose of antitoxin should be increased to 50,000 units, given intravenously; it seemed possible that with a more intensive use of antitoxin and with more effective drugs the fatality rate might be further decreased. The case reports from the Central Mediterranean Force have therefore been analysed to assess the effectiveness of the treatment at present recommended, and to examine the factors contributing to death in those patients who died in spite of such treatment. During the period under review penicillin was increasingly used in addition to or instead of sulphonamide drugs, and it is necessary to compare the effect of the combined treatment with and without penicillin before coming to any conclusion on the efficiency of the therapy now available.

Out of a total of 295 reports of anaerobic infections on Army Form I 1241 between the beginning of the campaign in Sicily and June, 1944, 185 reports have been considered to be typical of cases of gas gangrene, the main criterion being the infection of muscle, since bacteriological confirmation of a clostridial infection was not always given. It was shown in an interim analysis (MacLennan and Macfarlane, 1944) that there was good correlation between the data obtained in the early part of the campaign by personal investigations in the field and those obtained from the reports, and a further check is possible by comparison with the report made by Jeffrey and Thomson (1944) on 33 cases of gas gangrene in the C.M.F. treated with penicillin during the early months of 1944.

I. General Features

Method of Analysis.—The difficulties in the evaluation of therapeutic measures in gas gangrene have been discussed previously. Briefly, because of the many variables involved it is necessary to group together cases which are similar in nature and have received similar general treatment and then to determine within such a group the effect of the particular measure to be evaluated. The main facts which must be taken into account are the adequacy of the treatment with surgical measures, antitoxin, and drugs, and the site of the gas gangrene; other factors, such as the general facilities for evacuation and surgery, must also be considered.

Adequacy of Treatment.—The cases have first been grouped according to the level of treatment with surgical measures and antitoxin, in the classification used by MacLennan and Macfarlane (1944):

---

* Based on a report to the Subcommittee on Anaerobic Wound Infections, War Wounds Committee, Medical Research Council.

Class I: Treatment within 6 hours of diagnosis, including surgical measures (excision or incisions) and an initial dose of at least 50,000 units of polyvalent antitoxin, given intravenously.

Class II: Treatment later than 6 hours, *or* with a smaller dose or an intramuscular dose of antitoxin. (Cases in which the route or time of antitoxin dosage was not stated were included in this class.)

Class III: No surgical treatment, or no antitoxin.

This method of classification serves to distinguish in Class I the patients who received the treatment recommended, and the effectiveness of this treatment can be judged by the fatality rate in this class. The treatment in Class II can be broadly defined as being suboptimal in antitoxin therapy, for only 9 of the 78 patients in this class were placed there because of delay in surgical treatment; the difference in the fatality rates of Class I and Class II therefore mainly reflects the effect of prompt intravenous therapy with antitoxin.

Criterion of Adequate Treatment with Penicillin.—The treatment of gas gangrene cases with penicillin was usually systemic. For this analysis the criterion of adequacy has been taken as intravenous or intramuscular injection at the rate of at least 12,000 or 15,000 (Oxford) units every three or four hours. The total dose varied considerably, but the course was usually continued until death in the fatal cases and for three or four days in those which recovered. Some patients received, in addition, local treatment with penicillin, but four receiving only local treatment or an inadequate systemic course have been included in the "No penicillin" group.

It may be noted that the efficiency of the combined treatment including penicillin is being compared with the efficiency of the combined treatment including sulphonamides, and not simply with treatment by surgical measures and antitoxin, for practically all the patients received sulphonamide drugs in addition to or instead of penicillin. Any test of the value of penicillin, as such, in gas gangrene, is therefore bound to be severe, as the effect must be better than that of the sulphonamides in order to be demonstrable.

Site of Disease.—The cases have been grouped in two classes, according to the site of the gas gangrene: Class A, lower leg or arm; Class B, thigh, buttock, shoulder, or back. Approximately Class A is one in which the muscles have a good collateral circulation, and Class B is one in which either the possibility of a collateral circulation is poor or excision is anatomically more difficult.

Conditions for Treatment.—The cases in this series occurred over a period of nearly a year, during which there were considerable changes in surgical teams and in the conditions under which they worked. The high death rate in Sicily and in the early weeks of the Italian campaign may have been due in part to the inexperience of surgeons newly posted, and the rate was in fact falling towards the end of the year (MacLennan and Macfarlane, 1944). During the winter and until the opening of the offensive in May, however, most of the casualties occurred in the Anzio and Cassino areas; the field surgical units were practically in the line, and the conditions for nursing were so difficult that the amount of surgery was necessarily restricted, while the alternative of evacuation by sea or over bad roads was hazardous for patients liable to gas gangrene. Conditions such as these were no doubt mainly responsible for the number of patients in Class III; the disease was established on admission in many of these, of whom some died within an hour of arrival and others were judged unlikely to respond to treatment. The conditions in these areas improved by April, but were clearly inferior throughout to those prevailing during the May offensive. This information is derived from the reports of the Consulting Surgeon, A.A.I., who remarks: "Thus the battle began with an abundance of experienced forward surgeons. . . . The centres were well grouped, and the lines of evacuation short in time and in distance. . . . Never can conditions have been more favourable to good battle surgery."

The change in conditions is relevant to this analysis, for experience and early diagnosis are potent factors in the successful treatment of gas gangrene. In Sicily, and in the early part of the campaign in Italy, penicillin was mainly in the hands of experienced surgeons, since the technique of use was being explored; it apparently came into general use only during March (almost concurrently with the improvement in general conditions), for after this time approximately 80 to 90% of the reported cases received it. It seems probable, therefore, that the patients who received penicillin were on the whole at least as favourably placed for response to any treatment as those who did not receive it.

Inclusion of Cases with Complications.—The various complications among the 185 cases of gas gangrene in this series fall into two categories—those which may be sufficient in themselves as a cause of death, and those which are more immediately relevant to death from gas gangrene:

1. Complications sufficient as a cause of death:
   Head wound, 4; chest wound, 1; abdominal wound, 10; malaria, 2; pneumonia, 1; ? anaphylactic shock, 1. Total, 19 cases (10.3%), with 16 deaths.
2. Complications relevant to death from gas gangrene:
   Multiple limb wounds, 33; shock (failure to resuscitate), 4. Total, 37 cases (20%), with 27 deaths.

In three other cases death occurred suddenly, after an initial recovery, from either pulmonary embolism or secondary haemorrhage, which, like renal failure, can be considered as sequelae rather than as complications.

In all, 30% of the cases were recorded as having some complication, but examination of the data shows that the complicated cases are not unequally represented in the different groups, including the groups "penicillin plus" and "penicillin minus," and from a statistical point of view ther is no point in excluding such cases from the analysis. The data have therefore been tabulated inclusive of all the cases but where it seemed of particular interest the rates exclusiv of fatal cases with complications have also been given.

Throughout this report a difference is regarded as significan if it exceeds twice its standard error, in which case it woul occur by chance less than 5 times in 100 trials. As the numbe of cases in some of the groups is small, the standard errors ar high, and if a difference in rates is to be dissociated from pur chance it would have to be dramatic. It should be borne i mind, therefore, that a difference in rates which is not signif cant on these numbers might be significant with larger numbers but is probably not dramatic.

II. Gas Gangrene of Leg or Arm

The data for the patients with gas gangrene of the lower le or arm are shown in Table I, the cases being grouped accordin to the class of treatment with surgery and antitoxin, with an without treatment with penicillin.

Table I.—*Gas Gangrene of Leg or Arm*

Class of Treatment	Penicillin			No Penicillin			Difference ± S.E.
	Cases	Deaths	Fatality Rate (%)	Cases	Deaths	Fatality Rate (%)	
Class I ..	23	6	26·1	11	1	9·1	− 17 ± 1
" II ..	8	2	25·0	30	16	53·3	+ 28 ± 2
" III ..	1	1	100·0	11	10	90·9	− 9 ± 2

In no case is the difference in the death rate between the tw groups, penicillin plus and penicillin minus, statistically signi cant. In view of the small numbers in Class I, it is of intere to compare the death rates in this class with those of two oth groups, reported elsewhere, who received similar but not strict comparable treatment with surgical measures and antitoxi The penicillin-treated cases reported by Jeffrey and Thoms (which may overlap to some extent with cases reported o Army Form I 1241) include 12 cases of gas gangrene of t leg or arm. These patients are described as receiving full trea ment with surgical measures and antitoxin, including an intr venous dose of antitoxin before or at operation; 11 of the 1 patients recovered. Another series of cases reported previous (Macfarlane, 1943, Table VII) included 24 cases of gas gangre of the leg or arm treated promptly with surgical measures a antitoxin, with a total dose of more than 20,000 units of an toxin but without penicillin; 21 of these 24 patients recovere

It seems clear that in this type of case, given adequate trea ment with surgical measures and antitoxin, the expectation life is high. Many of these patients underwent amputatio and in view of the fact that in the majority of such cases the infection was eliminated from the body before administration of penicillin was begun it could hardly be expected that this treatment would make a difference to the death rate among them.

TABLE II.—*Amputation Rates in Gas Gangrene of Leg or Arm*

Class of Treatment	Penicillin			No Penicillin			Total in Class		
	Cases	Amptns.		Cases	Amptns.		Cases	Amptns. (%)	Fatality Rate (%)
		No.	(%)		No.	(%)			
Class I ..	23	17	73·9	11	8	72·7	34	73·5	20·6
„ II ..	8	8	100·0	30	27	90·0	38	92·1	47·4

The amputation rate among the 38 patients in Class II (shown in Table II) was over 90%, yet the death rate was 47%; this rate is significantly higher (27%±11.3) than the death rate among the 34 patients in Class I (20%) who received a prompt intravenous dose of antitoxin in addition to radical surgery. The combination of intravenous antitoxin therapy with surgery is clearly beneficial, and in considering its absolute efficiency it is of interest that the 7 fatal cases in Class I all suffered from some complication, which may have affected the issue.

III. Gas Gangrene of Thigh, Buttock, or Shoulder

It was noted previously that the poorer response to treatment in patients with gas gangrene of the thigh or buttock region might be due to the difficulties of excision, and it was certainly hoped that a more extensive use of antitoxin and of drugs highly effective against clostridia would lead to some improvement. The data for the C.M.F. cases of this type (Class B) are set out in Table III.

TABLE III.—*Gas Gangrene of Thigh, Buttock, or Shoulder*

Class of Treatment	Penicillin			No Penicillin			Difference; ± S.E.
	Cases	Deaths	Fatality Rate (%)	Cases	Deaths	Fatality Rate (%)	
Class I ..	13	5	38·5	11	6	54·5	+ 16 ± 20
„ II ..	8	6	75·0	32	26	81·3	+ 6 ± 16
„ III ..	6	6	100·0	31	31	100·0	No difference

Within each class of treatment with surgical means and antitoxin there was no significant difference in the death rate of the group treated and that not treated with penicillin. The mean death rate in Class I (24 patients, with 11 deaths) was 46% and in Class II (40 patients, with 32 deaths) 80%; the case fatality was therefore significantly decreased (34%±12.1) when the recommended treatment was given, but the death rate in this type of case was absolutely much higher than in the cases with gas gangrene of the leg or arm.

Jeffrey and Thomson (1944) report 18 cases of this type which received treatment with surgical measures and antitoxin similar to Class I, in addition to penicillin; of these patients 8 died—a death rate of 44.4%. In a previous series of cases (Macarlane, 1943) out of 11 patients of this type who received early treatment with surgery and antitoxin, with a total of more than 0,000 units, 6 died (54.6%). In spite of the best treatment which could be given in these circumstances, the death rate from gas gangrene in these sites remains about 45%.

IV. Conclusions on Effect of Treatment

The reduction in the death rate when antitoxin and bacteriostatic drugs were used as recommended in addition to surgical measures affords a striking testimony to the value of the combined method of treatment. It is clear, however, that the ancillary measures had their limitations in a type of case in which surgical excision of the affected tissue may be impossible. It does not appear that this limitation was due to inadequate dosage with antitoxin. The total dose of antitoxin given within 48 hours of onset to patients with gas gangrene of the thigh or buttock (Class I only) is shown in Table IV; similar figures for the group described by Jeffrey and Thomson are included. The death rates were not significantly less among the patients who received a total dose of more than 120,000 units of antitoxin; that is to say, there is no indication that a larger dose would have been of value as a routine.

TABLE IV.—*Dosage of Antitoxin in Class I Cases*

Series of Cases	Total Dose of Antitoxin in 48 Hours						Difference; ± S.E.
	Up to 120,000 Units			Over 120,000 Units			
	Cases	Deaths	Fatality Rate (%)	Cases	Deaths	Fatality Rate (%)	
C.M.F. Army Forms	11	7	63·6	13	4	30·7	32·9 ± 20·4
Jeffrey and Thomson	9	4	44·4	9	4	44·4	No diff.

With regard to the adequacy of treatment with penicillin the cases included in the penicillin group received a dosage which has been estimated to maintain a bacteriostatic level in the blood. In the C.M.F. cases there was no significant difference in the death rate between those who received penicillin systemically and those who did not, even among cases (Class B) in which a decrease might legitimately be expected if effective chemotherapy could compensate for inadequate surgical excision. This does not imply that penicillin is without value in the treatment of gas gangrene (still less that it is without value in the treatment of the patient, for the question of wound-healing has not been considered). Its value as a specific treatment, in the sense that the death rate was lower among those treated, is simply not proved. Whether penicillin controlled the bacterial infection is another matter, and one difficult to assess when several measures were often employed. It seems possible, however, that in a disease in which there is frequently a failure of the circulation through the infected area the local application of penicillin might be the more effective route.

The doses of antitoxin and drugs used appear to be adequate for their purposes and, on the whole, the opinion of surgeons seemed to be that the clostridial infection was controlled. If this was the case the question arises whether other factors were contributing to death in those patients who died in spite of apparently adequate treatment of the infection. In a number of cases the immediate cause of death was renal failure rather than a fulminating toxaemia, and the similarity between this type of case and the crush syndrome was pointed out by Jeffrey and Thomson. It is surely significant that the specific treatment recommended for gas gangrene was highly effective in a type of case in which radical excision was almost always carried out, and much less effective in a type in which excision was sometimes limited in extent. The hypothesis that a toxic substance is absorbed from muscle damaged by trauma or ischaemia is of course not new, but lately, with the recognition of the crush syndrome and the occurrence of massive limb wounds, it has aroused much interest. It is not unlikely that a necrotic bacterial toxin, such as *Cl. welchii* alpha-toxin, might accelerate or augment the liberation of a "muscle toxin" and thus have a potent secondary effect in addition to any direct action on a vital organ. In most cases the danger from such an effect would be minimized by early excision, but where excision is delayed the prevention of local damage may be of great significance. The existence and the nature of such a "muscle toxin," however, have yet to be demonstrated.

The importance of surgical excision of the affected tissue in gas gangrene has long been recognized, but as emphasis has been laid on this procedure chiefly in order to control the infection it seemed possible that bacteriostatic drugs might lessen the necessity for radical surgery. If the resorption of some toxic substance other than the bacterial toxin from gangrenous muscle is a factor in the severity of gas gangrene the situation is changed. On the one hand, if radical excision is practised the drug is probably superfluous as a life-saving measure; on the other hand, if the necrotic muscle cannot be removed and is a source of danger the drug may in fact control the infection—which is its virtue—without altering the outcome of the disease. To mention this possible limitation is of course not an argument against the use of drugs, for the control of the infection by any possible means is a primary necessity; but it may account for the fact that, with the numbers available, it has not been possible, either with the sulphonamide drugs or with penicillin, to show in the statistical sense that the drugs increased the expectation of life.

Summary

In a series of 185 cases of gas gangrene in the C.M.F. reported on Army Form I 1241 the case-fatality rate has been examined in relation to the treatment given. The combined method of treatment with surgical measures, intravenous antitoxin, and bacteriostatic drugs, when given as recommended, was highly effective in reducing the death rate in cases with gas gangrene of the leg or arm. The death rate in cases of gangrene of the thigh, buttock, or shoulder region was approximately 40% in spite of such treatment, even among those who received penicillin systemically. The findings suggest that the specific treatment was generally effective in controlling the clostridial infection, but that in cases in which surgical excision of the affected tissue is limited in extent some factor associated with the local damage to muscle may be contributing to the severity of the disease.

Thanks are due to the Director-General, A.M.S., for access to the reports. I am also indebted to Dr. E. Lewis-Faning for his criticism and the verification of the statistical significance, and to Sir Claude Frankau, Mr. B. W. Williams, and Prof. McIntosh for their comments on various case reports.

STAPHYLOCOCCAL PYOPERICARDIUM (COMPLICATING TYPHOID FEVER) TREATED WITH PENICILLIN

BY

H. BATHURST NORMAN, D.M., M.R.C.P.
Lieut.-Col., R.A.M.C.; in Charge of a Medical Division

AND

R. M. AINSWORTH, M.B., Ch.B.
Major, R.A.M.C.; Surgical Specialist

Because penicillin has been scarce, and because repeated injections are exceedingly trying to a debilitated patient, it is the rule that local application, whenever this will suffice, should be used in place of systemic treatment. It is recognized, too, that the use of penicillin does not in any sense replace surgical drainage, and that when pus is formed in any quantity it must be evacuated. In the case here described a staphylococcal infection of the pericardium supervened in the course of a very severe typhoid infection. The ensuing pyopericardium was successfully treated by the repeated aspiration of pus and the instillation of sodium penicillin into the pericardial sac.

Case History

An officer cadet, aged 26, was admitted to a military hospital on May 25, 1944, complaining of malaise, nausea, abdominal pain, and constipation for three days. On admission the temperature was 104° and the pulse rate 96. Apart from slight abdominal distension, no definitely abnormal physical signs were present. The urine was normal, and the white cells numbered 4.500 per c.mm. with a normal differential count. Health in the past had been unexceptionable. The most recent immunization with T.A.B. vaccine was in March, 1944.

The patient remained acutely ill, with high sustained fever. The abdominal distension became more marked and a troublesome cough developed. On May 29 *B. typhosus* was isolated from the blood in pure culture. About the same time a scanty macular rose-spot rash appeared on the abdomen. During the next few days his condition still further deteriorated. Constipation gave way to a persistent diarrhoea, with which vomiting was associated. The patient became stuporous and delirious. By June 4 serious dehydration was apparent, and three litres of normal saline were given by intravenous drip. Abdominal distension was pronounced, and there was considerable basal congestion of both lungs. But the fluid was well tolerated, and its administration was followed by a great improvement in condition.

By June 14 the temperature had practically settled, only a negligible evening rise persisting. Progress at this time appeared very satisfactory, but, disappointingly enough, four days later the patient again became seriously ill. The temperature was now 102°, and the pulse, weak and irregular, was 128. The physical signs were typical of a pericardial effusion, there being a definite paradoxical pulse and a positive Ewing's sign. On June 24 the pericardium was needled in the fifth intercostal space, half an inch inside the area of cardiac dullness; 50 c.cm. of thin pus was aspirated. This pus gave a pure growth of *Staph. aureus* on culture. The next day surgical drainage of the pericardium was attempted. A trephine hole was made through the sternum at the level of the fourth cartilage, but pus was not found in the pericardial sac. It was thought that this was due to the aspiration of the pericardium on the previous day.

On June 26 it was decided to needle the left pleura. Pus was not found, and the physical signs at the base of the left lung were those of collapse. The white cell count was 26,600 per c.mm., with an excess of polymorphs. The haemoglobin was 64%. The next day the pericardium was again explored through the trephine hole, and on this occasion pus was found and 4 oz. was evacuated. One pint of fresh blood was given by intravenous transfusion.

The pathologist had now reported the sensitivity of the *Staph. aureus* isolated from the pus withdrawn from the pericardium as being approximately the same as that of the standard "Oxford" *Staph. aureus*—i.e., zones of inhibition around cups containing one Oxford unit of penicillin per c.cm. were as follows: (1) patient's staphylococcus, 19 mm.; (2) Oxford staphylococcus, 28 mm. On June 28, therefore, penicillin therapy was inaugurated, 50,000 units of sodium penicillin being injected direct into the pericardial sac by means of a No. 5 rubber catheter. The superficial part of the operation wound had become secondarily infected, culture giving a profuse growth of *Ps. pyocyanea*. Before catheterization, therefore, the wound was filled with 1/1000 perchloride of mercury for a few minutes and then swabbed dry. This technique was found satisfactory, and there was no difficulty in the repeated passage of the catheter. The penicillin was introduced after aspiration of as much pus as possible and the wound subsequently packed to prevent leakage. The injection of 50,000 units was repeated on five further occasions, giving a total dosage of 300,000 units. The first three injections were given on successive days, and the last three on alternate days. After the third dose of penicillin the pus withdrawn from the pericardial sac was reported as sterile on culture.

On July 1 there was considerable improvement in the clinical condition. This improvement was maintained in spite of a sharp attack of diarrhoea, which responded satisfactorily to sulphaguanidine therapy. By July 10 the temperature was once again normal. On this day a further pint of blood was transfused. The haemoglobin prior to transfusion was 70% and the white cell count 14,500 per c.mm.

On July 17, however, there was a renewal of the fever, with the temperature rising to 102°. Some abdominal distension was still present and the pulse was again markedly paradoxical. The spleen was felt "two fingers" below the costal margin, tenderness and rigidity were noted over the right upper abdomen, and there were physical signs of a considerable effusion in the right chest. It was clear that fluid had once again accumulated in the pericardium, and 20 c.cm. of thin sterile pus was aspirated from it. Eighteen ounce of clear yellow fluid, sterile on culture, was also withdrawn fron the right pleura. Some improvement followed this, but in view o increasing dyspnoea it once again became necessary to aspirate both pleura and pericardium, 15 oz. being withdrawn from the forme and 15 c.cm. from the latter.

By Aug. 2 there was still an evening rise of temperature to abou 100°. Signs were now apparent of fluid in the left chest, and 12 oz of sterile heavily blood-stained fluid was aspirated. The spleen coul still be felt and the liver was palpable one inch below the righ costal margin. Slight oedema of the ankles was noted. Furthe exploration of the right chest produced only 3 c.cm. of fluid. N more could be obtained.

On Aug. 17 the patient was again transfused. In view of th persistent pyrexia a course of systemic penicillin was given, 15,00 units being injected every three hours for three days. This produce no improvement in the clinical picture, and it was abandoned, as was proving very exhausting. At this time another 14 oz. of blood-stained fluid was withdrawn from the left chest. The white ce count had dropped to 10,000 per c.mm., the haemoglobin was 75% and the red blood cells 3,650,000 per c.mm. The general conditio had improved. The blood pressure was 110/75, with no paradoxica pulse or evidence of cardiac tamponade. The liver and spleen wer no longer palpable, nor was there reaccumulation of the pleur exudates.

The evening rise of temperature still persisted, and there no developed a very tender swelling over the lower left costal cartilage A diagnosis of typhoid periostitis was made, and on Sept. 7 operation was performed under local analgesia, a transverse incision bei made over the costochondral junction. Thickened inflamed tissu were found with a small quantity of pus beneath the periosteu The bone was curetted and drained and the wound packed wi vaselined gauze. Thereafter convalescence was slow but consisten By Oct. 10 the patient was well enough for repatriation to th United Kingdom by hospital ship.

Comment

The occurrence of a staphylococcal pyopericardium in th case of a soldier already gravely ill with typhoid fever recorded. The successful treatment of this complication by penicillin instillation and repeated aspiration is described. The therapeutic result in the local treatment with penicillin depends upon whether it proves possible to maintain permeation with an adequate concentration of the drug. There are special difficulties in dealing with the infected pericardium. It is difficult to be certain that, when aspiration is done, adequate drainage in fact has been achieved. With extensive infection of the superficial wound of the chest wall it is hard to ensure that the pericardial sac is not contaminated with secondary invading organisms which are penicillin-resistant.

In the case of empyema thoracis similarly treated it is common to get a residual grossly thickened pleura and a rigid chest wall. Rib resection may be necessary to remove extensive fibrinous deposits from the empyema cavity. The end-results in pyopericardium, in which the scope of surgery is more limited, are likely to be less satisfactory. Attention is particularly directed to the long period during which the reaccumulation of sterile pus in the pericardium persisted.

Medical Memoranda

Impacted Foreign Body in the Bronchus of an Infant, causing Collapse and Obstructive Emphysema

The case here recorded is thought worthy of publication because of the occurrence of both collapse and obstructive emphysema in the same lung after impaction of a foreign body in the bronchus of an infant. The obstruction was successfully removed by bronchoscopy.

CASE REPORT

A male child aged 1 year attended the out-patient department of Belgrave Hospital for Children on Nov. 17, 1944, with a history of wheeziness and cough following a choking fit after eating some nut chocolate five days previously. On examination he was found to be healthy-looking and well nourished. There was diminished air entry with an impaired percussion note, as well as much diminution of breath sounds below the right clavicle over an area corresponding to the right upper lobe. The percussion note was hyperresonant over the lower part of the right side. There was some mediastinal displacement towards the right. The left side showed no signs. No abnormal physical signs were found in any other system. His temperature was 99°, pulse 154, respirations 48. He was admitted to the wards. A radiograph taken on admission showed complete collapse of the right upper lobe, with mediastinal displacement to the right and very well marked emphysema of the right middle and lower lobes. On Nov. 20 a radiograph showed increased collapse of the right upper lobe and increased emphysema of the right middle and lower lobes. He was transferred to the London Chest Hospital and bronchoscoped the same day by L. G. C.

Bronchoscopy Report.—Foreign body seen in the right main bronchus projecting into and completely blocking the right upper lobe bronchus but only partially obstructing the main stem bronchus. The foreign body was removed; it appeared to be a piece of nut.

A radiograph taken on Nov. 21 showed that the collapse of the right upper lobe had almost completely cleared, the mediastinum was nearly central, and there was no emphysema in the remainder of the right lung. On Nov. 23 the patient returned to Belgrave Hospital, where he made an uneventful recovery except for an attack of tonsillitis. On Dec. 28 radiographs showed that both lung fields were normal in appearance and the mediastinum central. He was discharged on Jan. 3, 1945, without any physical signs; pulse, emperature, and respiration were normal.

We wish to thank Dr. Norman Hill and Mr. V. C. Thompson for permission to publish this case.

URSULA JERRAM, M.R.C.S.,
Late Senior Resident House Officer,
Belgrave Hospital for Children.

L. G. CRUICKSHANK, F.R.C.S.Ed.,
Surgical Registrar, London Chest Hospital.

A Case of Aberrant Suprahyoid Thyroid Tumour

Aberrant thyroid tumours are recorded from time to time, but the occurrence of two separate tumours, one lying above the hyoid and the other just below the left cornua of the hyoid, s unusual.

CASE REPORT

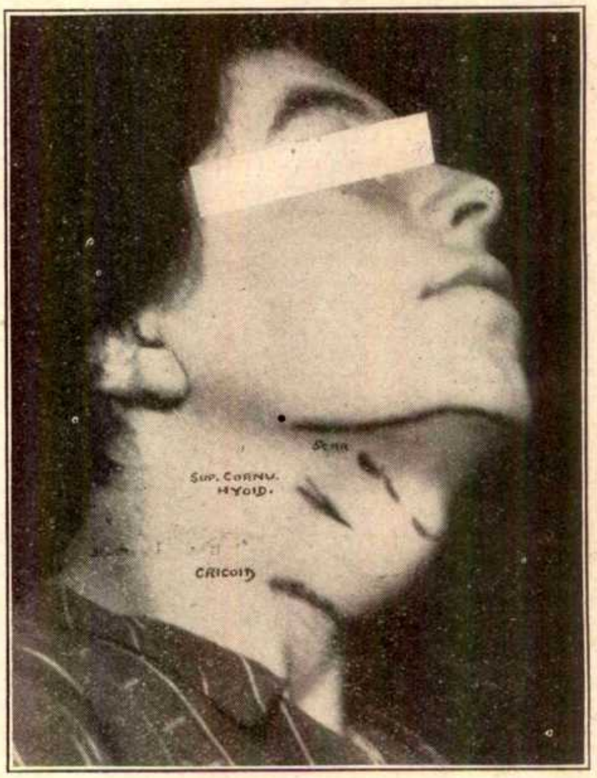
A spinster aged 30 attended the out-patient department and was ound to have a solid tumour, the size of a small hen's egg, lying in he midline between the mandible and the hyoid bone. She was a nervous, mentally deficient but pleasant young woman, who weighed over 9 st. and had a large fat face with prominent eyes. The fat was found chiefly on the trunk and face, and the legs and arms were thin in proportion to the rest of the body. She was of rather short stature, and her skin was dry, soft, and smooth. Menstruation was normal. Radiographs of the thorax did not reveal the presence of any thoracic tumour. A provisional diagnosis of a subfascial lipoma was made and the patient was admitted to hospital for operation.

Operation.—Under local analgesia a plum-coloured tumour was exposed and easily removed. It lay entirely above the hyoid, deep to the mylohyoid muscles, and there were no connexions which suggested remnants of the thyroglossal duct. About one inch from the left lower border, at the level of the superior cornu of the thyroid cartilage, there was a separate tumour the size of a small walnut, which appeared to be normal thyroid tissue. As the rings of the trachea could be easily palpated, and no thyroid gland could be felt, the second tumour was left alone. The patient was discharged seven days later.

The specimen had the appearance of a cystadenoma, into which haemorrhage had occurred. The pathological report, from Dr. Popjak, was as follows: "Atypical epithelial hyperplasia in ectopic thyroid. The tissue consists of solid masses of polygonal or cuboidal epithelial cells, having a pale-staining slightly granular cytoplasm and round nucleus, or small acini free of colloid. The latter are lined by a high columnar epithelium. At the periphery of the specimen there is a good deal of fibrosis and at the centre hyaline degeneration. There was no definite evidence of malignancy."

Post-operative History.—The patient was seen at intervals, and in a year lost 8 lb. in weight. The remaining tumour has enlarged and is now the size of a plum. Its consistence suggests cystic changes, and its removal may be necessary.

Moritz and Bayless (1932) state that the large majority of aberrant thyroid tumours are found in females in the third decade, and this case conforms with their findings. Lazarus and Rosenthal (1933) believe that 75% of aberrant thyroid is neoplastic, while Ward (1940) found 9 out of 12 of his cases to be malignant. Probstein and Agress (1936) consider that median tumours are usually simple and the laterally placed tumours malignant.



The photograph shows the situation of the present tumour, and the facies and distribution of fat.

I wish to thank Dr. Popjak for his report, and Mr. de Rynck for his kindness in taking the photograph.

H. A. KIDD, F.R.C.S.Ed., M.R.C.O.G.,
Medical Superintendent, Kingston County Hospital.

Reviews

HUMAN EMBRYOLOGY

Human Embryology. By W. J. Hamilton, M.D., D.Sc., J. D. Boyd, M.D., M.Sc., and H. W. Mossman, M.S., Ph.D. (Pp. 366; illustrated. 31s. 6d.) Cambridge: W. Heffer and Sons.

To the medical student of average ability, embryology is an extremely difficult subject for study. And well it may be, for, starting with microscopical sections of embryos, it involves two separate steps in mental reconstruction. First, sections which are approximately two-dimensional have to be strung together to form a semblance of the three-dimensional system, and then the three-dimensional systems require to be linked up in a time series in order to appreciate the gradual changes that occur during progressive development. The mental processes involve considerable powers of visualization, the aptitude for which (as every teacher of anatomy knows) varies greatly from one individual to another. Thus, to be really successful, a textbook of embryology needs to be amply and carefully illustrated, and this feature has been by no means a strong point in British textbooks of embryology in the recent past. Without doubt, therefore, the new textbook by Hamilton, Boyd, and Mossman will receive an enthusiastic welcome, for one of its outstanding qualities lies in the excellence of the illustrations. They are both numerous and exceptionally clear, and the frequent intermixture of accurate drawings of sections with realistic diagrams of reconstructed models should make it a relatively simple matter for the student to follow the text descriptions.

But, fine as the illustrations are, they are not the only outstanding character of this book. The authors are all embryologists of distinction and have themselves made important original contributions to their subject. In addition, they clearly possess a comprehensive knowledge of the literature. They have evidently set themselves out to produce a textbook which is readily intelligible to the ordinary student and at the same time accurate in detail and authoritative in interpretation. They have succeeded to the extent that their book will certainly be regarded as the students' standard textbook on human embryology in the English language. The descriptive accounts of embryological anatomy at various stages of development follow orthodox lines, and they are clear and detailed. Some may think that in certain sections they are perhaps too detailed for the average medical student, but here we sympathize with the authors in what must have been a very difficult task—the selection of material judged necessary for a liberal medical education. No two anatomists are likely to agree in these matters, and we consider that on the whole the authors have shown a judicious attitude to the problem. Each chapter is supplemented with a list of appropriate references to original papers to which the interested student may have recourse in order to amplify his knowledge, and the occasional discussions in the text on conflicting views should certainly stimulate the reader to do so. The inclusion of sections on foetal embryology is a welcome addition, expressive of the interest which this aspect of embryology has aroused in research laboratories during recent years.

We have suggested that this book will be accepted as a standard textbook. It follows, therefore, that it is likely to see a long run with a succession of editions. For this very reason the book is particularly worthy of a critical review, and we would offer the following suggestions for the consideration of the authors. The terminal chapter on comparative vertebrate development is the least satisfying part of the book, for it has too much the appearance of an appendix inserted as a sort of afterthought. It is too short and condensed to be of real value, and the diagrams which illustrate it are cramped and confused. Probably the chapter should be omitted altogether, and such information as it contains which has a direct bearing on the interpretation of human development inserted at the appropriate place in the main part of the book. In any case, comparative vertebrate development is such a vast subject as to require a separate textbook altogether. We would also suggest (if it is feasible) that the story of the dynamics of embryological development be more closely interwoven with the purely descriptive sections, so as to interrelate these aspects of developmental processes as closely as possible. We recognize that this is by no means an easy thing to do; yet it is an ideal to be aimed at if the student is to achieve a proper synthesis of the facts of development and the underlying processes of which they are the visible manifestation. Lastly, the book would certainly gain in value if the magnifications of the photomicrographs and illustrations of models were indicated in each case.

To review such a book as this is a real pleasure, and at the same time something of an honour. For it is a learned and erudite book, written and prepared with great care. Moreover, it is a welcome sign of a resurgence of anatomical science in this country which will go far to enhance the prestige of British Anatomy.

AN OUTLINE OF PHARMACOLOGY

Pharmacology. By Michael G. Mulinos, M.D., Ph.D. With foreword by Charles C. Lieb, M.D. Oxford Medical Outline Series. (Pp. 482. 25s.). London: Oxford University Press.

This is a useful book either for the student who wishes to learn quickly for an examination or for a doctor who wishes to have a book of reference to guide him in treatment. For example, on page 82 is to be found a section on tapeworm infestation. First there is a list of the three species which commonly infest man, and the origin and locality of these species. Next comes the diagnosis and after that a list of the symptoms; then methods of prophylaxis; then drug therapy, giving the details of preparing the patient, and the details of treatment, including second, third, and fourth methods of treatment should one method after another fail. Then are given details of the various drugs, in which is explained that oleoresine of aspidium *U.S.P.* is a dark-green liquid which is an ethereal extract of male fern; and the action and toxic symptoms are described. The book is thus a catalogue arranged under main headings A, B, C, etc., subheadings 1, 2, 3, etc., further divisions a, b, c, etc., and subdivisions (1), (2), (3), etc. This method of explaining the use of drugs is of great value to the house-physician who is learning to use them for the first time, when he needs something written in the style of a cookery book. It is, however, less suited to the use of drugs in a disease like syphilis, where treatment cannot be reduced to tabular form so easily. This is a book of moderate size and easy to read; it is conveniently interleaved with blank pages for notes, so that it is possible for anyone to carry the book with him and record his experiences in applying any method.

Dr. Mulinos thus presents another answer to the question "What is pharmacology, and how is it to be taught?" With the growing feeling that treatment is greatly in need of improvement, the answers become increasingly numerous. Some stress the theoretical background, others the practical application. Probably all are valuable if only the young physician is determined to discover from some authority what things can be done and is able to find time to try them.

BIOLOGICAL BASIS OF INDIVIDUALITY

The Biological Basis of Individuality. By Leo Loeb. (Pp. 711. $10.50 or 58s.) Springfield and Baltimore: Charles C. Thomas; London: Baillière, Tindall and Cox. 1945.

Individuality is used in this book to emphasize the distinctive unique features which a person possesses, and the physical features alone are dealt with. If we conceive of an individual as a mosaic of many tissues and organs, each one functioning and metabolizing in its own peculiar way, we may consider this mosaic of separate parts as the biological basis of individuality. There is, however, another basis which is comprised of properties common to all parts of the organism which can be discovered by observing the reactions of certain cells and tissues of one individual towards the tissues and cells of another individual. This is the theme of the 700 pages of this book.

Part I deals with tissue transplantation, and shows how the violence of reaction is in inverse proportion to the nearness of genetic relationship of the individuals concerned, though certain substances—e.g., hormones and vitamins—may not be destroyed when introduced into a strange host. The relationship of tissues within the individual organism is important in the study of the formation of antigens, and also of tumou formation. Part II deals with the phylogenetic and ontogenetic development of these individuality and organismal differentials from the lowest organisms and from the egg to the adult state. Part III deals with the differentials as found in the single cell, whether in protozoa, the leucocyte, or in the germ cells. Part IV deals with organismal differentials in tumours which represent modified tissues. Part V shows the part played by organismal differentials in the maintenance of the harmony of the organism as a whole, and in the interaction of the organs and tissues within the organism. Part VI deals with antigen and immune substances and how they are related to individuality differentials. Part VII shows the relation between the evolution of species and organismal differentials. Part VIII illustrates the significance of individuality differentials in the psychical social field; it is here that the concept of individuality had its origin. A full bibliography is appended.

This is a highly technical book and very comprehensive, and there is no doubt that it contains much valuable material for the study of many vital problems in heredity and pathology.

Notes on Books

For the third edition of *The Infant. A Handbook of Management* (H. K. Lewis and Co.; 4s.) Drs. W. J. PEARSON and A. G. WATKINS have added a section on preventive inoculation, and they also include a new table of vitamin requirements. A table on the daily allowances of essential food elements, based on the Hot Springs conference, brings this modest little book well up to date.

The Permanent Central Opium Board of the League of Nations has issued a pamphlet, *Pre-War Production and Distribution of Narcotic Drugs and their Raw Materials*, which is obtainable in this country from Allen and Unwin Ltd., 40, Museum Street, London, W.C.1, at 2s. This report summarizes and analyses the mass of world-wide information on drugs which the Board has received. It shows the importance of each country as a producer, and puts on record the quantities and method of disposal of the raw materials and manufactured drugs by both producer and consumer countries. The details will be of interest chiefly to technicians, but the main facts and conclusions are of wider concern.

Miss MARY V. LACE's book *Massage and Medical Gymnastics* was first published in 1936 with a foreward by Dr. James Mennell. A second edition appeared in 1941 and a third has now reached us (J. and A. Churchill; 12s. 6d.). During the past four years there have been many changes in physiotherapy, largely following the development of what is commonly known as rehabilitation. The emphasis on active rather than on passive treatment, which the popularization of this term has brought about, has been beneficial, but the simple basic movements should be thoroughly learnt by students. Though many suggestions about free exercises and useful occupations are added in this edition, the basic exercises are therefore retained.

Preparations and Appliances

A CONVENIENT TYPE OF OXYGEN TENT FOR PREMATURE INFANTS

Dr. L. SAGORIN, D.C.H., paediatric resident medical officer, E.M.S., writes:

It is now generally agreed that oxygen therapy has an imporant place in the management of certain types of premature infants (Hess and Lundeen, 1941; Tow, 1942), particularly those showing signs of an inadequately developed respiratory entre, with poor respiratory movements and consequent insuffiient oxygenation resulting in cyanosis and weak cardiac action.

To be of any use the oxygen must be administered early and by an efficient method. When given by "tube-and-funnel," nasal catheter, or by a tube in the mouth it is of very dubious value. The infant requires a high oxygen tension, and the best ype of apparatus is some form of tent or oxygen chamber.

As the standard type of oxygen tent for infant use was not always immediately available, some form of temporary apparatus had to be devised until a tent was available. The apparatus ound most suitable consists of a modification of the "hospital respirator." The rubber bellows and filter are removed and their attachment to the tent sealed off with zinc plaster. The xygen is introduced through a cylindrical tube at the side of the tent, and this inlet ends above the infant's head. The infant is placed in the tent; a hygrometer is inserted. The side-flaps re tucked under the infant and the tent covered with the requisite number of bedclothes, folded up to the window. The longitudinal fold is not tucked under the infant, as this unnecessarily raises the humidity in the tent and the concentration of oxygen. Temperature is maintained by hot-water bottles outside the tent.

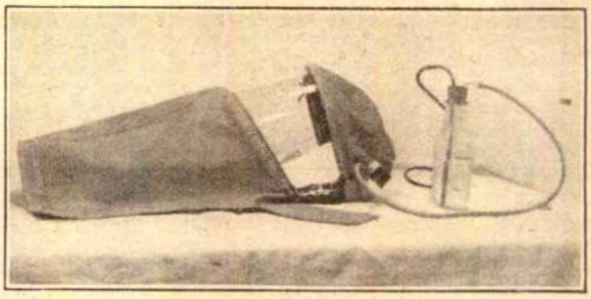

FIG. 1

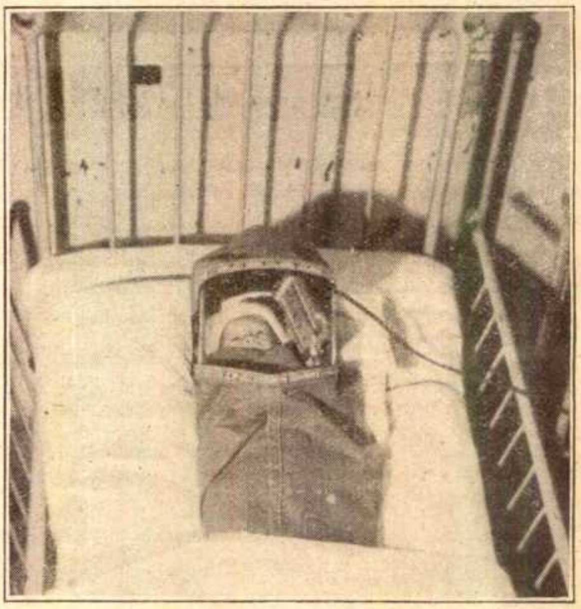

FIG. 2

Management.—An oxygen flow of 2 litres per minute produces a concentration of 80% in 10 minutes. After 3 hours the concentration diminishes to 65–70%. The carbon dioxide does not rise to above 1.5%, and an absorber is not necessary. The tent is opened at 3-hourly intervals for feeding and changing, and an adequate concentration of oxygen is always easily maintained. As a high percentage humidity is desirable for premature infants it is convenient to use a combined humidifier–flowmeter, when a humidity of 60–80% (depending on the weather conditions outside) is obtained. If the humidity rises above 80% the oxygen is run dry with the use of an ordinary flowmeter until the desired humidity is obtained.

Though originally introduced as a temporary measure, this tent has been found more useful, more practicable, and more economical than the larger type of canopy tent. With the latter the highest concentration of oxygen we could attain varied between 45 and 50%, and this with a flow of 6 to 8 litres per minute; furthermore, adequate humidity was difficult to maintain without the presence of basins of water in the tent.

The nursing staff find the infants easily accessible for feeding and changing. When necessary the tent can be transported in an ambulance or car for premature infants brought into hospital from outside. These tents have now been in routine use for the past nine months and have been found to be eminently satisfactory. Apart from premature infants under a birth weight of 3 lb. there have been no deaths during the first fortnight of life.

I am indebted to Dr. N. M. Jacoby for his constant advice and helpful criticism, to Dr. G. D. Grasby for permission to use the tents, and to Sister M. I. Wilcock and her nursing staff for their unfailing co-operation.

SYRINGES, SERUM, AND JAUNDICE

Jaundice, long known as a disease of campaigns, must now be regarded as a disease of clinics also. It is well known that our troops suffered a series of annual epidemics of infective hepatitis when they were fighting in the Middle East and North Africa,[1] but it is no less memorable that outbreaks of jaundice on a commensurate scale have occurred in this war in consequence of prophylactic and therapeutic procedures. In the American Army more than 28,000 men developed jaundice after yellow-fever vaccination in the early months of 1942.[2] The jaundice was traced to the human serum used in making up the vaccine, and on omitting the serum from the vaccine the outbreak of jaundice was abruptly halted. In this country the incidence of post-arsphenamine jaundice rose steadily during 1941 and 1942, until some clinics were recording jaundice in 46 and 68% of patients treated.[3] [4] MacCallum[5] suggested that the jaundice was due to transmission of infection from patient to patient by means of traces of blood left in the syringes, which at that time were not sterilized by heat between cases in most venereal clinics, and Bigger[6] demonstrated that the technique then employed was inadequate to prevent the passage of an infective agent. Salaman and co-workers[4] then showed that if a careful aseptic technique was used, with a sterile syringe for each patient, the incidence of post-arsphenamine jaundice could be reduced practically to zero, and as a result partly of this demonstration, partly of the introduction of penicillin, post-arsphenamine jaundice has joined the list of vanishing diseases. The belief that post-arsphenamine jaundice was due to the transfer of a virus from patient to patient in the syringes has been further strengthened since MacCallum[7] demonstrated by inoculation of human volunteers that an icterogenic agent is present in the serum in post-arsphenamine jaundice. Both yellow-fever–vaccine jaundice and post-arsphenamine jaundice must therefore be regarded as examples of the variety of jaundice now known as homologous serum jaundice.[8] The common factor is the contamination of the inoculation with small quantities of human plasma or serum which contains an icterogenic virus.

Another example of what appears to be the same variety of jaundice was recorded by Droller in the *Journal* of May 5, 1945. Droller studied an epidemic of jaundice which attacked 62 out of 450 patients attending a diabetic clinic. Analysis of the case incidence and incubation periods suggested that the epidemic was homologous serum jaundice, and the severity of the jaundice was in keeping with this suggestion. In the same number of the *Journal* Mendelssohn and Witts demonstrated that a virus could have been transmitted in the syringe used for obtaining blood for blood-sugar estimations, and it is noteworthy that the epidemic came to an end on discontinuing venepunctures. Similar epidemics of jaundice have been noted in other diabetic clinics,[9] [10] and also in rheumatism clinics[11] and sanatoria[12] where blood is often taken for estimation of the blood sedimentation rate. In none of these instances has it been proved yet that the blood contains a virus, as has been demonstrated by human transmission experiments in post-vaccinal and post-arsphenamine jaundice; but anyone dealing with an epidemic of jaundice of this type must now adopt the working hypothesis that the jaundice is due to transfer of a virus in the syringes used for injection or for withdrawal of blood samples, and must see if the epidemic cannot be brought to an end by improvements in aseptic technique.

If communal syringes are used in a clinic for the withdrawal of blood or the intravenous injection of drugs, a single carrier may in course of time infect all the patient attending the clinic, and, as already noted, as many as 68% of the patients may develop overt jaundice. Seeing tha the virus of hepatitis is highly infective, even in the smal amounts of plasma which are transmitted from patient t patient under these conditions, and that it offers consider able resistance to antiseptics, heat, cold, drying, and pro longed storage, the reader may well ask what are the risk when large amounts of whole blood, plasma, or seru are deliberately transfused. Whole-blood transfusions ha been used on a large scale for some years before the wa and there is little to suggest that they were at all common followed by homologous serum jaundice. Plasma an serum, on the other hand, are wartime expedients, an information about them has been difficult to collect owin to the dislocations of war, the rapid transfer of patient and the long incubation period of homologous serum jau dice. Early in the war a good deal of work was done c burns, and large amounts of plasma and serum were use in treatment. The clinicians were interested in the po sibility of liver damage from the burned tissue and t coagulant applications, so that it seems unlikely th homologous serum jaundice would have been missed; b here again late jaundice was not reported. Latterly, ho ever, experience has not been so favourable, and unpu lished figures suggest that homologous serum jaundice h occurred in as many as 10% of some series of patients whom blood plus plasma or serum has been given f resuscitation from war injuries. The mortality has be appreciable. To put matters in their proper perspecti we must remember that 96% of wounded men are n being saved, and the high recovery rate is in large part d to the development of transfusion.

We must conclude that in the present state of knowle transfusion inevitably carries a delayed hazard, and plas and serum should be administered with the same care dangerous drugs. In haemorrhagic and traumatic sh it is legitimate to take risks and to use dangerous remedies, but in other conditions in which life itself is not at stake the advantages of transfusion should be carefully weighed against the disadvantages. The risk might be expected to be proportional to the number of donors who have supplied the blood or plasma, and the mixing of icterogenic with non-icterogenic material may even increase its virulence.[13] On theoretical grounds, therefore, whole blood should be safer than plasma or serum, which are pooled products, and small pools of plasma or serum should be safer than large. Active research is being performed to settle these questions and also to determine if the virus cannot be inactivated during the processing of plasma and serum. In the meantime it is incumbent on anyone who gives a transfusion to record the case history, the details of the transfusion, and the identification numbers of the bottles of blood, serum, or plasma in such a way that both they and the patient can subsequently be traced. Whenever possible a patient who has received a transfusion should be kept under unobtrusive supervision for the next six months, and his medical attendants should be informed of the fact of transfusion. In this way a subsequent attack of homologous serum jaundice may be diagnosed in the pre-icteric stage, when prompt treatment by bed-rest may mitigate the severity of the illness.

The relationship of the viruses of homologous serum jaundice and infective hepatitis is still unsettled. Provisionally they must be regarded as two separate varieties of the same species, though it may prove that they are different phases of the same virus. The morbid anatomy of the two diseases is identical. They differ in the longer incubation period of homologous serum jaundice—approximately three months as compared with one month for the spontaneous disease—and in the greater severity and higher mortality of homologous serum jaundice. It is also uncertain whether patients suffering from homologous serum jaundice ever pass on the disease to others by contact, droplet, or excremental infection, and data on this problem should be collected and reported wherever possible.

THE TREATMENT OF BACTERIAL ENDOCARDITIS

In a series of papers S. R. Kelson, P. D. White, and other collaborators[14] analyse a large number of cases of subacute bacterial endocarditis seen at Boston and elsewhere in the U.S.A., and by grouping them into three therapeutic periods they give a clear picture of what has recently been achieved in the treatment of this disease. These papers provide the most important contribution to the literature of their subject for some years, and contain much information of interest from other points of view than the therapeutic. The first group consists of 250 cases seen in Boston between 1927 and March, 1939; only 33 of these were treated with sulphonamides; the other treatments employed were of forty-three different kinds. Only one patient made even a temporary recovery, to die of rheumatic carditis a year later; he had received no specific treatment. A second group between 1939 and 1944, all treated with sulphonamides, consists of 77 patients, of whom 6 recovered: 3 of these and 14 of those who died also received heparin. A combination of heparin and sulphapyridine, according to Kelson, affords the best prospects of success, and in a separate paper, dealing with another group of 34 patients, he records 8 apparent recoveries following this treatment, together with two others in which sulphadiazine, and both sulphadiazine and penicillin, were combined with heparin. A third small group in the main series comprises 9 patients treated with penicillin, 4 of whom have apparently recovered, while in 2 others the infection was suppressed, although they are now ill or dead from other causes.

A more complete picture of what penicillin will do in this disease is afforded by the observations of L. Loewe,[15] who has now treated 54 cases, with 14 failures and 40 successes, 37 of the latter being alive from 2 to 15 months later and 3 dead from other causes. It is an important feature of this author's method that every patient is also given heparin, not intravenously but subcutaneously in a gelatin menstruum from which slow absorption takes place; the necessary dose, usually about 300 mg. every second or third day, is determined for each case by estimations of the coagulation time, which is kept at between 30 and 60 minutes. He strongly advocates that penicillin should be given by continuous intravenous infusion in order to maintain a constantly adequate level in the blood. What that level must be depends on the sensitivity of the streptococcus in each case, and he recommends that the aim should be to maintain a concentration 5 to 10 times greater than the minimum required to inhibit the growth of the organism. M. H. Dawson and others[16] have previously reported very wide variations in the susceptibility to penicillin of different strains of streptococci from cases of endocarditis, and anyone who has studied these organisms knows that their characters are almost infinitely variable. The concentration of penicillin required to inhibit the growth of strains from Loewe's cases varied from 0.007 to 0.5 unit per c.cm; 3 strains exhibiting high resistance are said to constitute a distinct and hitherto undescribed variety, and treatment failed in the cases from which they were derived. The regulation of dosage on this principle resulted in variations in the daily dose between 40,000 and 1,000,000 units, and in the total amount given between 867,000 and the enormous figure of 48,930,000 units. An inadequate dose may cause the streptococcus to develop resistance; a forty-fold increase in its resistance was observed in one case. The duration of treatment should depend on that of the disease, but if possible a five-weeks course should be the minimum. Loewe considers that in cases of less than three months' duration, due to a reasonably sensitive organism and in patients in good physical condition, a good result may be expected in almost every case. It does not follow, of course, that such patients will be restored to normal health. Gross valvular incompetence must remain, and of those patients who have undoubtedly been cured of their infection during the past few years, a number have succumbed later to progressive cardiac failure.

[15] *Bull. N.Y. Acad. Med.*, 1945, 21, 59.

[16] *Proc. Soc. exp. Biol. Med.*, 1944, 56, 101.

Another American report on this subject is by M. H. Dawson and T. H. Hunter,[17] who have treated 27 cases in three groups. The first 5 were carefully selected favourable cases treated with penicillin only; since 2 of these relapsed but later recovered completely after a course of penicillin combined with heparin, administered in 1 case by Loewe himself, the next 15 were all given heparin by Loewe's method in addition to penicillin. Of these 15 patients, 11 recovered, 2 died, and 2 are still suffering from the disease. A final series of 7 cases has recently been treated, of which 5 had no heparin, with so far apparently equally good results; whether heparin is helpful is therefore a question still *sub judice*. Dawson and Hunter agree with Loewe that the dose of penicillin should be determined by the degree of sensitivity of the streptococcus—cases with hopelessly resistant organisms being rejected—and that a prolonged continuous course is necessary.

The treatment of subacute bacterial endocarditis with penicillin in this country is at present confined to specified institutions, as announced recently in this *Journal*. That this study should be kept on a research basis is obviously desirable until the best methods have been clearly defined. If those advocated by Loewe are finally accepted, this will always be a major therapeutic undertaking and restricted of necessity to hospitals where the fullest laboratory and other facilities are available. It will be interesting to see whether the ultimate verdict is pronounced in favour of combining the use of heparin with penicillin treatment. Heparin in endocarditis has never found much favour in this country, owing to its undoubted danger, but to judge by Loewe's present results the method of administration he now employs must have overcome this to a large extent.

DIAGNOSIS OF HAEMORRHAGE IN MAN

A few years ago most of us had the idea that collapse from haemorrhage was characterized by a rising pulse rate and, at a slightly later stage, a low blood pressure. This notion seemed to be firmly based on physiological grounds, in that a falling cardiac output would precipitate compensatory sympathetic vasoconstriction and cardio-acceleration through the sino-aortic reflexes. It came as a surprise, therefore, to realize that rapid bleedings in human volunteers up to a litre and over were accompanied by collapse reactions with marked bradycardia, and that these reactions became more frequent with the magnitude of the bleeding.[18-20] These vasovagal reactions have been analysed in detail by Barcroft and his colleagues,[21] who have shown that they are the result of "reflex" vasodilatation in the musculature of the body. The characteristic symptoms preceding and accompanying this fainting reaction include deep sighing respirations, yawning, feeling of heat and sweating, vomiting, waning consciousness, carpo-pedal spasms, and sometimes convulsions. The differential diagnosis of haemorrhage and fainting came to be meaningless. At a still later stage after haemorrhage, when haemodilution and anaemia have made their appearance, Sharpey-Schafer[22] has shown that another cardiovascular state occurs: the pulse is rapid and collapsing in type, while the cardiac output is up to double the normal. This state of affairs is commonly seen in patients admitted to hospital after recurrent gastro-intestinal bleeding, and is compatible with considerable reductions of blood volume.[23]

Three types of clinical picture after haemorrhage have thus been established: (1) the "classical" picture with rapid pulse and low blood pressure; (2) the vasovagal reaction; and (3) the late hyperkinetic phase, when post-haemorrhagic anaemia has developed. These varied reactions raise a host of problems for both the physiologist and the clinician. The vasovagal "reflex" and the high cardiac output with low blood volume cut right across current trends of thought on circulatory regulation based on animal work. The clinician also will have to observe the phenomena of transition between the various stages. Shenkin and his co-workers have made a further contribution to the problem by their careful studies. In the early phase of haemorrhage they subdivided the phenomena into the following three stages: (1) symptom-free at rest with pulse and blood pressure within normal limits, but undue acceleration of pulse on standing up; (2) intolerance of the upright position, which precipitates vasovagal syncope; (3) syncopal attacks with bradycardia even though recumbent. They also observed that when all the lost blood was retransfused 1½ to 2 hours after bleeding the blood pressure was raised 10 or 20 mm. Hg. above the value before bleeding.

All these data are of much interest and importance, and we shall expect soon to be able to see more clearly how the jigsaw puzzle fits together. Most of the experimental work involves acute and rapid bleeding. More work is required on slower rates of bleeding on volunteers, for this may resemble more closely what is usually seen in patients with gastro-intestinal haemorrhage.

ROAD ACCIDENTS

Before the war this country had a quarter of a million road casualties every year, with 6,500 deaths. During the war although there were far fewer vehicles on the road, the deaths have not been much below this figure. The return of the basic petrol ration, with its threat of an outbreak of mechanically dubious cars and unpractised drivers, is a sharp reminder that something must be done quickly to minimize the dangers of the road. Lord Leathers, Minister of War Transport, writing in the *Practitioner* for April said that the Government would soon announce some proposals, but that the whole community must make a combined effort. Medical practitioners come into contact with the road problem from several aspects. As the Minister pointed out, they know the suffering and trouble that accidents cause; as motorists they are familiar with the dangers and they can personally influence many of the motoring public. They have a special responsibility in certifying that applicants for licences to drive public service vehicles are medically fit to do so. No medical examination is imposed on applicants for an ordinary licence, and Dr. Douglas Kerr, writing in the same issue, thinks the present declaration of fitness has little value and tha private drivers should be obliged to produce a medica certificate similar to that of a public service vehicle In this opinion he is supported by Mr. Eric Farmer's researches in accident-proneness. As drivers are no examined after accidents, statistics concerning the responsibility of unfit drivers for accidents are, he says, fallacious Without some such information medical examiners wi continue to work largely in the dark, especially if, a Dr. Hugh Dunlop thinks, most of the "borderline" disabilities, as distinct from the definitely incapacitating ailments, are mental and temperamental. Recklessness indecision, and lack of road sense are more easily detected in the police court than in the consulting-room or even at the driving test; but when detected they ought, if serious, to be recognized by disqualification. Drunkenness, according to Prof. Sydney Smith, has been greatly exaggerated as a source of accidents; but alcohol is a potential danger in quantities too small to be appreciable in clinical examination, and in his opinion the problem of the drinking driver would be greatly simplified if the law assumed a driver, as it does in many of the United States, to be "under the influence" if his ability has been lessened in any degree by alcohol. Small improvements in motor-car design (leading, for example, to better braking, vision, comfort, and ventilation), such as Mr. J. F. Bramley and Dr. N. T. Glynn, of Austins, enumerate, will perhaps eliminate more danger than will any revolutionary change; such a change, they say, may be more necessary in the design of the roads. The effects of accidents may be mitigated, as Mr. Charles Noon and Mr. William Gissane show, by extending the provision of blood transfusion and sulphonamide drugs, and by organizing accident centres similar to those which have long proved their value in industry.

As the Minister observed, the most disturbing aspect of the road problem is the high toll it takes of children. Over the decade before the war the figures were improving; but the war brought a setback, and the figure is now about a hundred deaths a month in the age group between 3 and 8 years. Dr. Percy Stocks's figures from the General Register Office[1] show that children did not benefit by the wartime estriction of road traffic, and that their need is especially urgent. Training of children in road sense on the lines suggested by Dr. Muriel Hughes in the *Practitioner* will have to be intensified and greater attention given to protecive measures such as guard rails and play centres. The legal attitude to compensation for road accidents ought, in Mr. Harcourt Kitchin's view, to be radically changed, and he compensation and rehabilitation of victims should form part of a communal insurance scheme and not depend on a dilatory and expensive legal tussle between insurance companies. Finally, readers may think that the statistics of oad casualties will never have much quantitative meaning until the number of victims are correlated with the number of vehicles on the roads.

THE HORROR CAMP

Accounts in the lay press of German concentration camps and the report of the Parliamentary delegation have confirmed what many people knew years ago—namely, that the Nazis, with cold inhumanity, were systematically torturing and slowly exterminating Jews and political enemies. It is well, therefore, to put on record in this week's *Journal* an account of the conditions in Belsen written by one of the medical men engaged in resuscitating its diseased and starved victims. Apparently only a small proportion of the inmates of Belsen were German Jews. The rest were Jews from the various countries occupied by Germany at the height of her recent expansion. The German policy seems to have been one of complete and utter neglect, so that the inhabitants of the camp, deprived of all care and the common decencies, should die of starvation and disease. The results of this policy are described on page 814 y Dr. W. R. F. Collis, a Dublin physician.

It seems to be established beyond doubt that German doctors gave intravenous infusions of benzol and creosote, and we are informed that the apparent reason for injecting benzol was the induction of a paralysis in the victim which ould "justify" sending him or her to the crematorium. When British doctors and nurses subsequently tried to administer casein hydrolysate to the starving wretches they cried out in terrified expectation of being sent to the crematorium. It is very hard indeed for people living in this country to realize this terrible example of man's inhumanity to man, and it requires a mental effort to grasp the enormity of such behaviour in civilized Europe. What is peculiarly distressing is the knowledge that German doctors—presumed to be educated men—should so completely deny the humane tradition of their calling, a tradition laid down by the school of Hippocrates and reaffirmed since then by countless generations of medical men the world over. We should of course not fall into the error of supposing that all German doctors are like the doctors in Belsen. But we should be doing a profound injustice to the thousands upon thousands of tortured Europeans if we too easily forget what has happened. It will be some time before we can look upon German doctors as men imbued with the ideals of medicine common to civilized countries—ideals so magnificently sustained by the British doctors, nurses, medical students, and orderlies now cleansing this Augean stable of Nazi horror.

WARTIME RESEARCH IN DAIRYING

The National Institute for Research in Dairying is one of the research institutes founded by the Board of Agriculture as part of the scheme of agricultural research formulated under the Development and Road Improvement Fund Act, 1909. Reading was chosen as the centre of dairy investigation, and in 1912 the Institute was established at University College, Reading (now the University of Reading). In 1920 it acquired the Shinfield Manor Estate, four miles away. The last annual report issued was for the year Oct. 1, 1939, to Sept. 30, 1940. Two years ago it was decided that the publication of some connected account of the work done during the war years should not be too long delayed, and a report has now been published outlining the research activities in the triennium Oct. 1, 1940, to September 30, 1943. This record shows that much of the time and energy of the staff of the Institute has been given to problems created or intensified by war conditions, the solution of which problems would increase wartime efficiency in production, handling, distribution, or manufacture of milk and milk products. Some of these problems have been solved to the advantage of the country and the dairy industry; some are still under investigation; some wait on fundamental research before a solution can be found. The war has repeatedly underlined the need for fundamental and long-range research in certain directions in dairy science. Experience on the farm in wartime has emphasized that there is still much to be learnt about the breeding, feeding, and management of dairy cows for consistent high yield and quality of milk either when, as now, imported concentrates are scarce or when the supply of feeding stuffs is normal. The events of the war have supported the view, expressed many times in the past by the Institute, that the physiological approach to many problems of dairy husbandry needs greater emphasis both now and in the future. Another need brought to light by wartime conditions is for improving farm dairy appliances and machines. Practical wartime difficulties in the dairy industry have again and again stressed the importance of a wider and more accurate knowledge of the micro-organisms which either enter unasked or are pressed into service at different stages of milk production, handling, and distribution, or in the manufacture of cheese, butter, and dried milk. As the director, Prof. H. D. Kay, says, "Quite fundamental to any system of control or assessment of the marketability of milk or to a steady improvement in the quality of milk reaching the public is objective research in this field of dairy bacteriology . . . the post-war research work of the Institute must be on a larger scale and attain a wider scope than anything conceived before the war."

BELSEN CAMP: A PRELIMINARY REPORT

BY

W. R. F. COLLIS, M.D., F.R.C.P., F.R.C.P.I., D.P.H.

The following extract from an appreciation of the situation by the senior medical officer after 24 hours' contact with the camp will serve to illustrate the state of affairs at the beginning.

GENERAL LAYOUT

"The camp is separated into two distinct portions—Camps 1 and 2. Camp 1 is a hutted encampment housing approximately 22,000 females and 18,000 males. Camp 2 consists of a series of brick buildings and houses approximately 27,000 males. The inhabitants of these camps are of mixed nationalities, with Russians and Poles predominating. Czechs, Belgians, French, and Italians are also present.

CONDITIONS PREVAILING

The following is a brief account of the conditions seen on first entering these camps on April 17, 1945. It is impossible to give an adequate description on paper.

Camp 1.—A dense mass of emaciated apathetic scarecrows huddled together in wooden huts without beds or blankets in many cases, without any clothing whatsoever in some cases. The females in worse condition than the men, their clothing generally, if they have any, only filthy rags. The dead lie all over the camp and in piles outside the blocks of huts which house the worst of the sick and are miscalled hospitals. Approximately 3,000 naked and emaciated corpses in various stages of decomposition are lying about this camp. Sanitation is non-existent. Pits, with, in only a few instances, wooden perch rails are available in totally inadequate numbers, but the majority of inmates, from starvation, apathy, and weakness, defaecate and urinate where they sit or lie, even inside the living huts. There is no running water or electricity. All water is being brought in by our water trucks.

Camp 2.—Conditions in this camp are vastly improved in comparison with Camp 1. The inmates are housed in buildings, 600 to a building of 150 capacity. Sickness in this camp is much less and the death rate is about 10 a day. The inmates appear better clad and generally less emaciated than in Camp 1, though signs of starvation are everywhere. An attempt is being made to bury the dead.

DISEASES PREVALENT

Camp 1.—Riddled with typhus and tuberculosis. Gastro-intestinal infections are very common and are probably enteric and simple gastro-enteritis. No cholera or dysentery has been diagnosed. Erysipelas, scurvy, and starvation disorders are prevalent.

Camp 2.—Enteric, tuberculosis, erysipelas. There is no typhus in this camp."

Actually the state of affairs was worse than described above: for instance, when the corpses were more accurately counted the figure was nearer 8,000 to 10,000 than 3,000. In many cases the dead lay in naked walls of bodies around the huts, many of which were filled, literally filled, with the dead and the dying. Next to nothing had been done for these people for months. For a week they had had almost no water. There they lay, either three persons to a bunk designed to hold one or on the floor, in foul rags drenched in excreta, covered with lice. Death came chiefly through starvation, typhus, tuberculosis, and dysentery: 500 a day were dying from disease, and the guards killing more. In Camp 1, covering an area of 0.8 mile long by 0.4 mile wide and containing a large portion for administration and another for the crematorium and "accessories," were kept 40,000 human beings confined most of the time to the huts on pain of being shot.

Into this foul place came the British troops. The S.S. guards were got under control and forced to bury the dead and clean up the worst of the filth. The Hungarian guards were also employed, and an S O S for help sent out. In the meantime the following British medical units were sent to the camp by the D.D.M.S., Second Army, Brig. H. L. Glyn Hughes, together with a contingent of the armed Forces, including military Government detachments, and began the colossal medical task of transforming a death-trap into a hospital, though it could not be regarded as a commitment which came strictly under the Army Medical Services, but the dictates of humanity required quick action: 32 C.C.S. (Lieut.-Col. J. A. D. Johnston, R.A.M.C.); 11 Light Field Ambulance (Lieut.-Col. M. W. Gonin, R.A.M.C.); 163 Field Ambulance (Lieut.-Col. M. E. M. Herford, D.S.O., R.A.M.C.); 30 Field Hygiene Section (Major P. J. Fox, R.A.M.C.); 76 Field Hygiene Section (Major F. R. Waldron, R.A.M.C.). Some days later these were reinforced by No. 9 General Hospital—600 beds (Col. A. R. Oram), and these have been followed up by another C.C.S. and another general hospital of 1,200 beds.

The work carried out by these medical units under the direction of the S.M.O. Camp, Lieut.-Col. Johnston, produced results which have to be seen to be believed. The setting up of hospital accommodation of 17,000 beds in ordinary barrack buildings is one of the monumental tasks undertaken and accomplished. Beds, bedding, drugs, dressings, and a hundred and one other items of hospital equipment had to be found from one source or another, whilst nursing and domestic aid on a large scale had to be recruited and organized from among those internees capable of rendering assistance, and also from German sources. Only the superb initiative and untiring energy displayed by Lieut.-Col. Johnston made this feat possible. The Field Hygiene Section were meanwhile tackling the problems in hygiene which abounded in this camp of horror. Supervision of the clearing away of corpses and filth, with which the camp area was literally covered, and the disinfestation by D.D.T. powder of the 40,000 inmates of the camp were among the manifold duties which fell to their lot in the struggle to control infection and prevent its spread. The antityphus measures undertaken were directed and controlled by Capt. W. A. Davis, U.S.A. Medical Corps (Consultant in Typhus attached to 21st Army Group from the U.S.A. Typhus Commission). The work carried out by the Field Hygiene Sections and Capt. Davis has undoubtedly resulted in preventing a widespread epidemic of typhus.

About a week after the camp was uncovered a contingent of the British Red Cross arrived and were immediately thrown into the fray, doing anything and everything that they were asked. The women, under the leadership of Sisters Silver-Jones and Beardwell, were sent into the hospital area to take care of the first 600 patients admitted, most of whom were in a dying condition, covered with suppurating sores and almost all suffering from dysentery and many from typhus. The men took on the job of driving the now patients from the horror camp to the human laundry and then to the hospital. About two weeks later 100 medical students arrived and, under the direction of Dr. Meiklejohn, of U.N.R.R.A., took over the major job of feeding the internees in the horror camp. The stench, the foulness, which these young men endured is quite impossible to describe. Gradually the huts were got into order and the patients thinned out, partly by removal and partly by death and the camp was divided into two areas—one known as the Horror Camp Hospital, in which treatment of a medical nature is now being undertaken. In those huts outside the Horror Camp Hospital one or two students with 0 to 5 internee nurses look after 200 to 400 people who have not been medically sorted out. In the huts of the hospital area of the Horror Camp (Camp 1) three medical students look after some 150 patients, assisted by internee nurses and Hungarian guards. In a small division of a hut containing 8 to 10 patients may be found two cases of typhus, one or two cases of advanced tuberculosis, and three with dysentery. The complications mos often met with in the typhus patients are thrombosis, gangrene and bronchopneumonia. Cerebral symptoms are rare and usually fatal. Among the pure famine cases are many with oedema, gingivitis, pigmentation (? pellagra), emaciation, and profound lassitude. These medical students have done and are doing a work of epic gallantry and are worthy of all honour

The daily death rate in the camp, which was approximatel 300, fell very shortly after the arrival of the students and is now approximately 60. There is no doubt that the provisio of 40 tons of dried milk and of the necessary protein hydrolysate and glucose, and the supervision of the special feeding have resulted in the saving of thousands of lives.

The accompanying map gives the general layout of the camp as it now exists.

Camp 1 (the Horror Camp) is now practically empty. A da or two should see the last of the inmates cleared from th ordinary huts to either No. 1 Camp Hospital or to the hospit- proper. The Horror Camp will then be burned.

Camp 2.—Part of this camp is now under the control of a Army General Hospital, with already nearly 2,300 patients. ■

is rapidly expanding to 3,500. The larger portion of Camp 2 is still under the control of the original C.C.S. and consists of the main hospital area, containing 11,200 patients. It is divided into squares of five houses, the whole square accommodating approximately 700 patients. Each square is under the control of one medical officer from the R.A.M.C. Each house of 150 patients has one Swiss or internee or German doctor in charge. Each square has only one or two British trained nurses, the rest being either internee nurses or German nurses. It has been found necessary due to the lack of doctors and nurses from home to employ German doctors and nurses. No doubt the additional medical skill thus added have proved beneficial in a general sense, but the patients are naturally terrified of being looked after by Germans even under supervision, remembering how they were tortured in the past. It has been established that patients were often given intravenous infusions of benzol and creosote by the German *medical* staff, so that now, when the doctors approach with hydrolysate for intravenous infusion, the patients often cry out begging not to be taken to the crematorium. The main squares (see map) are for general treatment, while the three blocks at the back are kept for maternity patients and children. Probably nowhere else in the world at the present moment, certainly in no maternity hospital, have obstetricians to deliver women who are actually suffering from typhus at the time of their confinement, but here this is quite ordinary. The difficulties facing the staff have been truly appalling, but now very few women are getting puerperal sepsis, though many of the babies are still going down with neonatal sepsis.

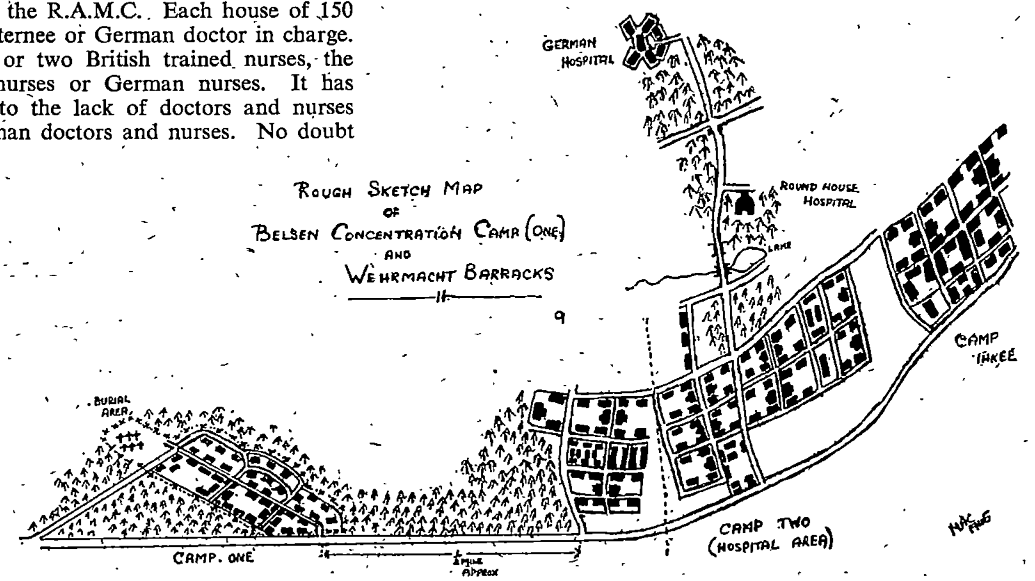
The Children's Blocks are the happiest in the whole camp. Many of the children are emaciated, showing the utmost marasmus, and many are sick; but also many are now beginning to recover, and, strange though it may seem, these, particularly the children under 7, do not show the terror symptoms which are perhaps the most terrible aspect of the adult patients' mental state. Already they are laughing and smiling again. Many are going to recover altogether. But our responsibility will not end then, for most have no homes to go to, no parents, no ordinary future. Surely somewhere in the world there are people who will come forward and care for these children and give them a home again.

In the general squares of the hospital area the main treatment up to the present has been that of feeding those in the extreme famine condition. Dr. Janet Vaughan and her team are doing invaluable work with intravenous hydrolysate while making important scientific investigations; but it is not easy to give an intravenous infusion with one hand and a bed-pan with the other, and little can be expected from these specific treatments. Few of the important scientific problems can be tackled properly until sufficient nursing facilities can be obtained.

In the hospital area it is still necessary to nurse patients with open tuberculosis and typhus in the small overcrowded wards containing other patients. Without *x*-ray apparatus diagnosis is often only provisional.

Camp 3.—This area contains approximately 8,000 persons. They are supposedly well or at least convalescent and have been ransferred from the other camps. They are able to walk and generally able to look after themselves; but many are pitiably weak still, and now quite a number are getting sick and being ransferred back to the hospital once more. Typhus has broken out now in Camp 3 quite seriously, and the problem of the management of this vast collection of persons from the social and medical points of view is one of the most difficult facing the directors of the camp.

If the map is referred to again two other hospitals will be seen—the Round House Hospital and the German Hospital. These have not yet been opened, though over 1,200 German patients have been removed from the latter, and it is now being got ready for admission of the patients from the camp. One wing is at present being used for the treatment of a number of orderlies and R.A.M.C. personnel who have themselves contracted typhus in the course of their duty. The opening of these new hospitals will greatly help the more advanced types of medical and surgical therapy.



Finally comes the immense problem of rehabilitation of these poor, abused, broken people. First the demands of their bodies must no doubt be met, but many are as wasted in mind as they are in body. Here expert workers are necessary, and vast quantities of books in all languages—Russian, Polish, Yugoslavian, German, and French, together with all kinds of sewing equipment, such as needles, thread, thimbles, etc., for the women; and much besides. The number of French internees cannot be more than 200, and all whom one speaks to who are recovering are full of hope and thinking only of the day of their return to France; but many thousands of those from the East, particularly the Poles, have no homes to go to, have apparently no future, no hope. The problem of what to do with these forsaken, almost lost, souls is immense, but one which if not tackled and solved will make all our efforts here mere waste of time, for then it were kinder to have let them die than to have brought them back to mere existence and more suffering in a hostile world where they have no longer even a hope of being able to compete in the struggle of the survival of the fittest, and must inevitably go down.

Conclusion

This is a brief preliminary report of Belsen Camp to give the medical profession in Britain some idea of the medical problems involved. It is a complete understatement. No words can describe the stench of decaying faeces, rotting bodies, and burning rags, which in the first weeks one could begin to smell miles from the camp, and it can but be left to the imagination of the medical men who read this article to appreciate what the doctors, nurses, and students at Belsen have endured and accomplished.

Since the camp was taken over from the Germans more than 20,000 internees have been buried; some 30,000 are left, of whom 11,200 are in the main hospital area. Now the Horror Camp is being rapidly emptied and the first emergency problem of hospitalization at Belsen has been accomplished, though an enormous task lies ahead if these poor people are to be cured and rehabilitated. It will be possible to repatriate those who are fit to be moved to their own countries, where further hospitalization and rehabilitation will be a matter for their respective peoples; but there will still remain a very large number, possibly thousands, of Stateless and homeless people whose welfare, both medical and general, and ultimate assimilation into normal society must remain as an almost insoluble problem, for years to come.

All honour is due to the R.A.M.C. and the doctors, nurses, and medical students of the British Red Cross and Order of St. John, under whose umbrella a large number of people of different nationalities have worked in perfect harmony. Particular mention must be made of the Swiss doctors and nurses who arrived by air and immediately went straight into action in the traditional manner of their countrymen whenever the cause of humanity is to be served. Nor must the gallant efforts of the internee doctors and nurses be forgotten. Many were sick and weak themselves, but, forgetting their tired and wasted bodies, they have worked and fought beside our medical personnel to their utmost power. Finally, the part played by the orderlies and other British soldiers must also be remembered. Their courage and kindliness were amazing, and not a few of them now lie dangerously ill, having contracted typhus while cleaning-up the filth and helping the lice-covered patients.

THE TASKS OF U.N.R.R.A.

MEDICAL SERVICES IN LIBERATED COUNTRIES

Dr. Andrew Topping, chief of the Health Division of the European Regional Office of the United Nations Relief and Rehabilitation Administration (U.N.R.R.A.), Col. R. E. Butler, its chief nutrition expert in the Balkans, and other members of the Health Division staff have lately returned from visits to certain of the liberated areas of Europe. They recently met representatives of the medical press in conference, when some very candid and enlightening statements were made.

Difficulties of the Administration

Dr. Topping said that the original programme of U.N.R.R.A. was framed on the supposition that it would play an important part in the reorganization of medical services throughout the liberated countries, but it was not appreciated that for this purpose certain essential priorities must be secured and support given at the highest level by the subscribing Governments. U.N.R.R.A. had not been able to obtain these priorities, with the supplies, shipping, and man-power necessary for its elaborate programme. Many Governments had been extremely half-hearted. Statements had been current that U.N.R.R.A. was not doing its job, but no one had explained that it was not its province to relieve liberated countries during the active military period when the various armies engaged were supposed to be dealing with civil problems. The problem of transport and supply so far as the civil populations were concerned had proved impossible for the armies, whose prime aim had obviously to be the successful prosecution of the war, but this fact should have been stated and the slur upon U.N.R.R.A. removed.

The Administration, Dr. Topping further explained, had had to cope with a severe shortage of medical and nursing services. One of the sections in its constitution provided that subscribing Governments should release any in their employment who were considered essential for U.N.R.R.A.'s activities; but in fact, while many local authorities deserved praise for releasing temporarily some of their key personnel, considerable difficulties had been found in obtaining the people who were wanted. It had also been expected that the liberated countries of Europe would require expert help in the reorganization of their medical services, and in fact a senior health officer had been appointed to each country; but while these officers had been courteously received and friendly relations had been established, and their help in enabling supplies had been appreciated, they had been given no specific functions in the reorganization, and their presence was, to put it bluntly, looked upon as the price to be paid for essential medical supplies.

The European Picture

Concerning the conditions in France and Belgium, Dr. Topping said that in many respects they were not as bad as they had been represented. It had been stated that there was great shortage of doctors in Belgium, but in fact doctors there were in adequate supply, and indeed a number had been recruited by U.N.R.R.A. with the full co-operation of the Ministry of Health. The position in Holland was considerably worse than elsewhere, and in Greece the position was serious, largely owing to a lack of appreciation by the Government of the need for sufficient medical and nursing services. Italy also was not getting an adequate diet, but in this respect it was little worse off than before the war. The future of these countries from this point of view depended upon forces stronger than U.N.R.R.A., chiefly upon the resources available for overcoming world food shortage.

As for countries within the Russian sphere of influence, Dr. Topping said that a mission had been ready to go to Poland and Czechoslovakia for many months, but so far it had been impossible to obtain permission. Although a mission had now entered Yugoslavia, it appeared that the authorities there looked upon the presence of U.N.R.R.A. personnel as little more than a nuisance and were not according them reasonable facilities. Yugoslavia had asked for a team of plastic surgeons, complete with anaesthetists, dentists, and nurses, and U.N.R.R.A. is investigating the possibility of meeting their wishes.

Solid Achievements

Nevertheless, U.N.R.R.A. has some great achievements to its credit. Dr. Topping mentioned the organization of very large camps in the Middle East and North Africa. At one time there were more than 60,000 refugees under the Administration's control, but these were gradually being sent back to their own countries. Another achievement was the establishment of friendly relations with the medical profession in the various countries. Concerning the control of displaced persons in Germany, U.N.R.R.A. had undertaken to provide 450 teams, each with doctor and nurse, and 205 were in the field already, working under military control. A good deal of difficulty had been experienced in getting together these teams, for it was possible only to get older people or the medically unfit and those who could be spared from their ordinary jobs. The recruiting net had been cast very wide. A number of doctors had been recruited from France, Belgium, Poland, and Czechoslovakia, and it was hoped to obtain others from Eire, Switzerland, and Sweden, and from Austrian refugees in this country.

Dr. Topping added that Sweden had been very helpful i offering to take 10,000 displaced persons, sick people, and children. The country had already received 20,000 peopl from Germany, mostly Norwegian and Danes. The difficult would be the hard core of people, expected to number at leas half a million, who had no country.

The Extent of Malnutrition

Prof. V. P. SYDENSTRICKER, the American nutritional exper told the conference that in Paris and Brussels, although ther was hunger and misery, there was no serious state of starvation. In Western Holland, the portion of the country liberate early in May, actual starvation did prevail, and the ration ha fallen to an extremely low level. Loss of weight was foun to a significant degree in the town populations, and in the poo districts of towns where close observations had been mad 10% of the people were suffering from famine oedema. List of these people had been prepared, and they were visited b officials and given extra food when it was available, and th Dutch were prepared to carry their own relief as soon a supplies appeared. He also spoke of experiences with protei hydrolysate. Small experiments he had carried out personall had been successful, and in Holland the first reports wer excellent. He had been told that at Belsen the experiment wa not successful, the people suspecting a new form of tortur It was only when people were too ill to take milk and gru that protein hydrolysate was used.

Col. R. E. BUTLER spoke of his experiences in the camp mainly for Yugoslavs and Greeks, in the Near and Middle Eas While there were minor deficiencies, by and large the childre were in good condition. In Greece itself the picture was no different from what it was in 1940–1. The growth of the blac market, to thwart the German authorities, and the advent the Swedish–Swiss Red Cross, had resulted in a marked improvement in nutritional standards. In the hospitals, amon the many patients brought in for injuries, there were few wh exhibited any marked degree of malnutrition. Thanks to th Red Cross, the situation was in control in Athens and Salonik He had seen no cases of famine oedema in Greece, though was reported that the children were under weight. In Ita minor deficiencies were apparent, but the age-weight figures had not been seriously disturbed. If supplies were continued as already allocated, no grave position should arise.

Infant Welfare and Epidemiological Work

Prof. R. R. STRUTHERS, of McGill University, a paediatrician attached to U.N.R.R.A., added some observations on his recent visit to France and Belgium. He said that children in the age-group 1–3 years had been well provided for; the neonatal death rate was not much higher than before the war. The frequency of miscarriage was rather higher than normal, but nothing like it was in 1941–2. Breast-feeding of infants was not carried on for as long a period as usual, but this might be due to the desire of the mothers to get back to their factory employment. The birth weights of infants were comparable with the pre-war figures. In Holland the children looked comparatively well, but lean. The only place where he had encountered acute difficulty was in the South of France, along the Mediterranean coast, where supplies of food and milk were inadequate.

Dr. N. M. GOODMAN gave some account of the new international conventions sponsored by U.N.R.R.A. at the time when the International Office of Public Health in Paris was under German occupation. U.N.R.R.A. received and dispatched as quickly as possible epidemiological information and had set up bureaux in London and Washington, the former to deal with notifications from Europe, the Middle and Near East, and Africa, and the latter with notifications from the Americas and the Far East. Among the other duties of the Administration was to authorize yellow fever vaccines to be recognized internationally, and with the consent of the French Minister for the Colonies, tests were to be made on French soldiers going to the Far East. It was a new departure in medicine that an international body should be authorized to test and approve vaccines and the institutes at which they were made.

EMERGENCY RATIONS FOR POLAR FLIGHTS

For the Polar flights made by the R.A.F. Lancaster *Aries* it was decided that in case of a forced landing in the Arctic regions the aircraft should carry emergency rations for the crew of nine sufficient to last 28 days. These were designed and prepared by the Low Temperature Research Station of the Department of Scientific and Industrial Research, in close consultation with Wing Comdr. Macrae, of the R.A.F. Institute of Pathology, and Wing Comdr. Winfield, of the R.A.F. Institute of Aviation Medicine, who was the medical officer on the flights. For this purpose the normal rations available were not altogether satisfactory, as they would have been too weighty and bulky. Thus the use of dehydrated foodstuffs was indicated, and, in view of our development of compounded food tablets, an approach was made by the Air Force authorities with a view to a ration being specially made for the job in the Low Temperature Research Station.

Compounded Dehydrated Foods

If the aircraft was forced down there was a good possibility that some of the aviation spirit could be salvaged. A stove had been designed to burn 100 octane spirit, and its use for cooking and for melting snow and ice to reconstitute dehydrated food was possible. Clearly the amount of fuel available was not unlimited, and the ration had to be so designed to use it economically, and in case no fuel was saved a substantial proportion of it could be eaten dry and be palatable in that form.

The ration pack was designed so that most of the food was in the form of blocks of compounded dehydrated foods. These consist of mixtures of dehydrated foods with added sweetening and flavouring materials where appropriate, so that each is a ready-made meal requiring only the addition of water. They are fabricated into tablets of standard size (usually 2 in. by 2 in. by 0.9 in.). Two of their virtues are that they need only to be wrapped in high-grade waxed films or papers and that their standard size facilitates the assembly of mixed rations, while very little space is wasted as compared with circular cans. One of two processes is employed. Tablets containing dried foods of large particle size such as dehydrated meat or vegetables are made by compressing the mixture in a hydraulic press. The pressed block can be crumbled easily in the hand and reconstituted, when any lumps are broken up by the swelling of the larger particles. Where the particle size of the material is much finer, as with spray dried powders such as milk or egg, compressed blocks of this kind would be very difficult to crumble, and, furthermore, lumps escaping crumbling would remain as unreconstituted lumps and mar the smoothness of the product. Thus they are prepared by casting the mixture hot into moulds with added molten fat. The fat binds the particles when cold, and the block can be dissolved by adding it to the boiling water. The heat of the water melts the fat and the enclosed particles of food go into solution without any lumps being formed. The texture of these blocks is such that many of those containing milk powders are palatable when eaten as sweets.

Menus for Four Days

A sufficient range of these blocks had been developed and tested to enable four different menus to be prepared to relieve the monotony of the diet. Just as everyone eats bread and drinks tea every day, so some items were included each day or on more than one day in the four, but it is thought that the variety was as great as in a normal wartime household menu. The possibility of increasing the number of varieties still further was rejected as it would have complicated the job of production. The menus finally agreed upon were:

	Day 1	Day 2	Day 3	Day 4
Breakfast	Porridge Toasted cheese Biscuits Butter Milk	Porridge Scrambled egg Biscuits Butter Cocoa	Porridge Herring Biscuits Dripping spread Milk	Porridge Scrambled egg Biscuits Dripping spread Cocoa
Mid morning	Tea	Tea	Tea	Tea
Lunch	Meat & vegetable stew Fruit Biscuits Butter Tea	Cod pie Biscuits Butter Cheese Coffee	Meat & vegetable stew Semolina pudding Biscuits Dripping spread Tea	Curry Biscuits Dripping spread Cheese Milk
Supper	Meat soup Beef & tomato Mashed potato Cocoa	Beef Mashed potato Fruit Tea	Tomato soup Mutton and onion Mashed potato Cocoa	Beef Potato Semolina pudding Tea
Snacks	Boiled sweets Chocolate	Boiled sweets Raisin chocolate	Boiled sweets Chocolate	Boiled sweets Raisin chocolate
Total calories per man	3,430	3,380	3,400	3,550
Total weight of food per man	708 g.	705 g.	715 g.	706 g.
Total weight of fat per man	185 g.	184 g.	177 g.	213 g.
% fat	26 g.	26 g.	25 g.	30 g.

The computed total weight on this basis was 393 lb. plus 3 lb. for immediate wrappings of the blocks. It was found that rations for two days could be packed into a standard 4-gallon can which not only was most convenient as a master container but also could be gas-packed to ensure that the food remained in the best condition possible. The fourteen cans increased the total weight to 435 lb.

Assembly and Labelling

To simplify unpacking and utilization and to reduce the amount of labelling the 7 or 9 blocks of each item required for one day were held together by adhesive tape in a vertical stack. The stacks were quite rigid, and, thus often, where there was space between them and the side of the can, a single block or a biscuit was inserted as a key, thus avoiding the need to fill the whole space with packing. These stacks of blocks were assembled and labelled before the packing of the cans began, and this procedure made the packing operation much simpler—the whole ration laid out on the laboratory bench was quite an impressive sight, though it was difficult to realize that it represented rations for 252 people for one day.

The weight of 715 g. achieved in practice includes, in addition to water and roughage, some 8 g. of salt and 13 g. of tea. It is therefore considered that, for a ration which gives three normal meals a day, it would be virtually impossible, with the materials available at present, to reduce the weight of the ration further. The tinplate cans used and the immediate wrappings contributed some 40 lb. to a total of 435 lb. gross, but this is very modest compared with most emergency rations, even when master containers are excluded. The robustness of the package and the fact that it could be gas-packed were advantages which more than counterbalanced the extra weight. The only other possibility would seem to be in the use of light metal alloys for such a purpose.

These types of food may be of great value for future polar expeditions.

Reports of Societies

PHYSIOLOGY AND TREATMENT OF STARVATION

EXPERIENCES IN WAR-STARVED EUROPE

A meeting of the Section of Medicine of the Royal Society of Medicine was held on May 29, under the chairmanship of Dr. **GEOFFREY EVANS**, for a discussion on the treatment of starvation conditions, and in particular on the use of protein hydrolysate. The discussion was preceded by the projection of Ministry of Information films depicting conditions in the German concentration camps.

Physiological Basis of Starvation Symptoms

Dr. H. E. **MAGEE** (Ministry of Health) said that between 1927 and 1933 he was engaged in studying the functions of the alimentary canal, particularly absorption by the small intestine, in animals. Absorption was fundamental to all the other nutritional processes. Failure in absorption was the essential lesion in starvation. Evidence pointed to progressive decline in the efficiency of absorption with increase of fasting period. Many experiments proved that deprivation of food, so far from increasing the functional efficiency of the epithelium of the small intestine, actually diminished it, also that the metabolic functions of the body were slowed by fasting. The small intestine was the great portal of entry of nutrients into the body, and if the essential cells of this viscus were destroyed, as in extreme starvation, the administration of food acted merely as an irritant, causing diarrhoea and dehydration. The aim must be the restoration of structure and function of the intestinal epithelium, and as this could not be done by giving food by mouth, suitable "building stones" must be given by vein. Enough glucose must be given, preferably before the proteins, to cover the body's energy needs so as to prevent the amino-acids administered from being used up for energy purposes. Sufficient B vitamins must also be administered to cover oxidation of glucose.

Loss of the protective function of the epithelium laid the intestine open to infection by organisms present in the food, and would explain the presence of ulcers so frequently found in persons dying of starvation. The work of Elman and others in the United States had shown that suitable hydrolysates could be used in the treatment of starvation arising out of pathological conditions which prevented the consumption, digestion, or absorption of food administered in the ordinary way. Dr. Magee had felt that this method of treatment would be of inestimable benefit to people suffering from acute starvation, though at the time this work was brought to his notice (1943) he had not contemplated the possibility of cases of starvation requiring such treatment coming to this country. He added that the Ministry of Health had set up emergency supplies of hydrolysate in Whitehall and in the regional offices for immediate use.

Conditions in the Channel Islands

Dr. Magee, who had just returned from the Channel Islands, said that there he saw two cases of extreme emaciation in adults, and these, with another case, had been evacuated to this country. He also saw a number of other adults, including German prisoners, in varying stages of recovery from nutritional oedema and emaciation. The history in all these cases was the same. As the diet became more vegetarian, and therefore more bulky and fibrous, the patients became increasingly unable to eat food of any sort, oedema set in, and then persistent diarrhoea and vomiting. In the more severe cases even milk was not tolerated. In some cases which came to operation or necropsy, volvulus of the caecum was found, with spastic contractions of the transverse colon, and ballooning of the part proximal to it. The large and, more rarely, the small intestine were thinned out to an extreme degree, and seemed to consist mainly of the serous coat. Ulcers of the large intestine were also sometimes seen.

The surgeons on the Islands had informed him that at first the perforation of peptic ulcers was relatively common, and subinvolution of the uterus had been frequent during the occupation. They also said that the incidence of appendicitis was much lower during the occupation than before it. Since the liberation the bulk of the people had been suffering from constipation, sometimes very obstinate, and the whole medical profession in the Islands deplored the return to white bread.

Preparation of Hydrolysates

Dr. P. **CUTHBERTSON** (Medical Research Council) said that in planning to treat cases of starvation it was urgent that adequate protein intake should be available, or, if the ability of the body to break down protein into its constituent parts were lacking, as in advanced cases of starvation, that the constituent amino-acids should be at hand. Dr. Magee had stressed the changes in the columnar epithelium in fasting, and it was to be supposed that the enzymes suffered a similar change, though this was not quite established, and even in the most advanced stages of starvation it was still possible to get patients to sip proteinaceous fluids and to obtain some protein synthesis.

Interest in protein hydrolysates dated from 1913, when Henriques and Anderson carried out some experiments on goats, injecting into the vein of the goat a hydrolysate formed by a pancreatic extract of goat flesh, as a result of which nitrogen equilibrium was achieved. Amino-acids given in the form of hydrolysates brought about a positive nitrogen balance. He mentioned various methods by which hydrolysis could be induced in proteins: (1) Proteolytic enzymes of pork pancreas; here the longer the digestion went on the greater the proportion of amino-acids. (2) Papain, a proteolytic enzyme from the melon tree; digestion at 50° C. was rapid. (3) The acid H_2SO_4, splitting the protein into amino-acids, but in the course of this development tryptophan was lost. Casein hydrolysis had also been used; its great drawback was unpalatability.

Dr. Cuthbertson demonstrated the sets as made up by the Protein Requirements Committee of the M.R.C. Each set included, besides instructions and records, ten bottles of 5% hydrolysate, one tin of glucose–vitamin mixture, five bottles of plasma and serum (dried), and five bottles of 10% glucose in pyrogen-free water. These packages were meant for the treatment of patients too ill to sip fluids by mouth. The idea was that the glucose–vitamin mixture should be given by gavage (drip nasal feed) and the protein hydrolysate by vein. By the evening of the third day it was thought that the patients would be got on to skim milk plus glucose by mouth. The plasma had proved to have considerable value; it increased the osmotic properties of the blood, and perhaps reduced the hunger oedema. On the other hand, if there was a considerable demand by the tissues for protein, that protein might be rapidly used up. In addition to the intravenous sets, units were being put up for 16 complete treatments, providing 50 grammes of hydrolysate and 50 grammes of glucose.

A Complex Picture of Many Unknowns

Dr. **HUGH S. STANNUS** said that protein hydrolysates had sprung rather suddenly into prominence, and might attain the unenviable position of being regarded as a cure for all ill. Associated with extreme emaciation was a marked loss of protein in the tissues, and to save life the first essential was to restore protein. The giving of protein hydrolysates was only one among other methods which might be used to attain this end. From 20 to 30 different amino-acids had been isolated from animal and plant proteins; 8 to 10 were essential to human needs. Combinations of these amino-acids, in different order or amount, with some omitted and others added, made an almost infinite number of different proteins possible. It had been estimated that there were 1,600 types of protein in the body of man. The amino-acids were the stones or bricks with which each cell built its own structure.

The conditions in starvation, to meet which protein hydrolysate therapy had been introduced, made a complex picture of many unknowns. If the patient could swallow, digest, and absorb the requisite amount of protein this might be supplied in some suitable form such as reconstituted dried skim-milk powder by mouth, or, if he could not swallow, by nasal-tube feeding; but if he were unable to digest, then protein hydrolysate should be given by mouth or by gavage, and if he could not swallow or digest or absorb, then resort must be made to intravenous administration of protein hydrolysate.

This conception, however, had been rather shaken in his own experience when called upon to advise upon the treatment of a repatriated prisoner of war who was in the last stages of starvation, with an extreme degree of emaciation and dehydration, and regarded by his R.M.O. as unlikely to live another day. He had also a Flexner infection, and the diarrhoea persisted in spite of sulphaguanidine. He had difficulty in taking his milk diet. It seemed to be a case demanding intravenous hydrolysates, but none were available, and the man was therefore given glucose-saline intravenous therapy, a crude liver extract parenterally, and teaspoonful feeding with powdered liver substituted for the milk diet. The response was dramatic, and a second case responded in a similar manner.

Among the considerable number of returned prisoners of war detained in hospital whom Dr. Stannus had had the opportunity of examining, the signs suggestive of protein deficiency had been almost universal. Many showed, in addition, all kinds of signs combined into mixed syndromes recognizable as indicative of vitamin deficiency—conjunctivitis, cheilosis, annular stomatitis, glossitis, change in the hair, paraesthesia, acrocyanosis, altered reflexes, "crazy pavement" skin, and pellagrous eruptions. Anaemia was common in some of the megalocytic type.

Conditions at Belsen Concentration Camp

Dr. JANET VAUGHAN, who was one of a small team of workers sent out at the end of April by the Medical Research Council to test the relative value of hydrolysates, skimmed milk, and serum in the treatment of starvation, gave a moving account of the conditions she found at Belsen camp. She first paid a tribute to the R.A.M.C. personnel. The amazing courage and gallantry of those who first went in to tackle what must have been one of the worst medical problems that had ever been put up to anyone deserved high praise. There were on the field at the beginning a field ambulance, a casualty clearing station, and a mobile pathological laboratory to deal with literally thousands of starving and dying persons, and the way in which they rose to the occasion was unbelievable. She herself and her colleagues arrived late in the day, after the first fortnight, and she would always feel it a great privilege to have seen what courage and kindliness could do in face of such difficulties.

The problem was a twofold one: to determine whether the hydrolysates worked, and whether they were practicable. The answer to both questions was quite definitely in the negative under the conditions found in the concentration camp. They had compared the administration of amigen, an acid hydrolysate, by intravenous injection; serum given in normal concentration and twice concentrated (because it was found that at the prescribed dose they could keep no one at a positive nitrogen balance; hydrolysate used orally, both in the standard dose of 50 grammes daily and in the double dose: and a milk mixture in the standard dose of 120 grammes daily.

Laboratory conditions were good, but hospital conditions most primitive. The hospital was a German barracks, in a filthy condition, furnished with wooden beds and straw pallets. Each floor had about 100 patients. There were two water taps on each floor, but sometimes no cold water for days together. Hot water was obtained by means of a primus stove. During the first week candles were the only artificial light. Nursing at first was done by the less ill women in the camp, who had, of course, no training, and by members of the Hungarian Army, who performed every function under the supervision of one English sister responsible for four big blocks. Food was supplied from big central kitchens under the supervision of one Red Cross worker in each kitchen. Preparation and distribution were relatively primitive, and the feeding of this mass of ill humanity was an extremely complicated problem and made one feel that it would be better to provide the personnel for the distribution of food instead of carrying out elaborate therapy. The people were of all nationalities, with no common language. Patients severely ill were admitted to the number of 700 to 1,000 a day. They went straight to what was called the "human laundry," really the laundry of the barracks, where they were laid on tables and scrubbed by German nurses to remove the caked dirt and faeces of months. She and her colleagues would go to the laundry to pick out cases which they thought would be useful for their purpose. They chose men who were grossly emaciated, too weak to get themselves off the stretcher. A snap diagnosis was made, to avoid patients with tuberculosis or dysentery. All of them had diarrhoea and all had oedema of the feet. Some cases showed gross famine oedema. The pathological facilities did not suffice to cope with 1,000 cases a day, but it was clear that although there was some Flexner dysentery, the majority of the cases gave no micro-organism.

In the group of cases dealt with the haemoglobin level was, on the whole, surprisingly high considering the gross deficiency of the blood. The mean figure for 21 men was 66.5%. This included three very low figures, and one very high figure in a collapsed patient, and eliminating these four abnormals, the mean figure was 69%.

Results with Intravenous Therapy

Dr. Vaughan first described the results with intravenous therapy. Five patients were given amigen; they took it well, and had no reaction. Four of them did well; the fifth, with famine oedema, showed no improvement at all. Three patients had oral hydrolysate by intravenous injection; two of them showed no improvement, and the third was very much worse at the end of 2½ days. This was a boy aged 18, with gross ascites, which became worse under treatment. It was thought essential to raise his plasma protein in the hope of drawing fluid from the tissues, and in the succeeding 24 hours he had two litres of twice concentrated serum, with striking improvement. Three other patients were treated with serum, and all did extremely well. Those with oedema improved, and among those who had had no oedema there was a general sense of well-being and increased facility in moving about.

The workers felt no doubt that if it was possible to use intravenous therapy on a large scale under these conditions serum was preferable to hydrolysates. The theoretical explanation was that with the serum there was much more protein with relatively little fluid. There was danger in pushing fluid into these starved people. A litre of fluid given intravenously, together with whatever they wanted to take by mouth, was probably sufficient. One of the reasons why serum was likely to be more valuable than hydrolysates was because with the latter not enough could be given to bring about a positive balance.

The hydrolysates given by mouth proved to be the worst fiasco of all. The substance had a very unpleasant flavour, and many patients having taken 300 c.cm. curled up and preferred to die rather than take any more. One or two vomited all that they had taken. Two took the whole amount, but with devastating clinical results. One man, who was most co-operative, on the second day of his oral hydrolysate passed at least half a bucketful of watery brown stool and had gross abdominal discomfort. An endeavour was made to give it by nasal drip or oral tube, but the patients regarded this as a new form of torture, and it was difficult to explain to them what it was intended to do.

On the other hand, milk and glucose–vitamin mixture answered extremely well. There were not more than 5% of the patients at Belsen who would not take fluids by mouth. But it was essential to flavour the milk. Many of these patients had sore ulcerated mouths. Mouth washes were out of the question under such conditions, and milk, given for three days with a sore mouth, was not very satisfactory. It was found useful to flavour the milk with tea or coffee, but, of course, other flavourings might be used. Starving people craved not only for food but for familiar food. There was no difficulty in getting them to take milk, and no abdominal discomfort followed, but it had to be given frequently in small feeds, which was very difficult because of lack of nursing staff, and they could not help feeling that it was better to employ nurses to give small frequent feeds by mouth than to set up drips.

Dr. Vaughan added that she was speaking only of hydrolysates in the type of patient whom they had had to handle at Belsen. She did not mean that hydrolysates given perhaps in conjunction with food and under proper nursing conditions might not play a great part in the medicine of the future.

Nitrogen Balance

Capt. J. A. F. STEVENSON, R.C.A.M.C., referred to some nitrogen balance studies undertaken at McGill University. It was the experience of most workers that in the period of increased nitrogen excretion following fractures and burns, if the intake by mouth were increased it resulted in very little change in the nitrogen balance, for as the intake went up the output also went up, so that there was still a negative position. Some workers reported that they could prevent the nitrogen balance from falling by using protein hydrolysate intravenously, and accordingly various amino-acid mixtures were tried out. He exhibited a chart illustrating some experiments with amigen given intravenously to people who were healthy and well-fed but had sustained injury. The results went to show that amino-acids given by vein were treated by the body in exactly the same way as food given by mouth. In the ordinary case there was very little distinction so far as the body was concerned between the results of the two procedures.

The discussion was wound up by a few remarks by Prof. R. B. HAWES, who said that the unhappy circumstances which had made this discussion significant might not be without their value if they taught politicians and others the importance of protein supply. It was Army experience that if there had been a low protein intake in early life, no matter how the men might have developed subsequently, nor how well-fed they might be, these people were the first to show a lowered resistance and to go down with pneumonia or other infection.

Correspondence

Inguinal Hernia

SIR,—Dicey, in the preamble to his famous classic *The Law of the Constitution*, quotes the following remarkable passage written by Burke in 1791:

> "Great critics have taught us one essential rule. . . . It is this, that if ever we should find ourselves disposed not to admire those writers or artists, Livy and Virgil for instance, Raphael or Michael Angelo, whom all the learned had admired, not to follow our own fancies, but to study them until we know how and what we ought to admire; and if we cannot arrive at this combination of admiration with knowledge, rather to believe that we are dull, than that the rest of the world has been imposed on. It is as good a rule, at least, with regard to this admired constitution (of England). We ought to understand it according to our measure; and to venerate where we are not able presently to comprehend."

I would commend this passage to Squad. Ldr. J. B. Kinmonth, who, in the *Journal* of May 5 (p. 642), speaks disparagingly of the filigree operation in the treatment of inguinal hernia and also of the results published by Mr. Percival Cole. May I be allowed the courtesy of your columns to give my own experiences in this matter.

Since 1938 I have carried out the filigree repair upon upwards of 80 cases. The filigree technique has been reserved for difficult cases, and the age incidence has been mainly between 40 and 65. Most of the cases have been large inguino-scrotal herniae or herniae of the direct type. Herniae *en glissade* has been present in two instances. The only recurrence I have had has been in a member of the N.F.S. who had been operated upon twice before elsewhere; in this case the recurrence was only slight. Paradoxically speaking, I would welcome a few recurrences, as I am anxious to practise this side of the technique. Apart from this one case, no others have come to hand. Most of the cases have been carefully followed up, and every patient has been asked to report should there be any recurrence. I cannot agree with your correspondent that the recurrences and failures go elsewhere; my experience in other branches of surgery has been that they do come back. In this connexion I well remember a member of the staff of a teaching hospital, who, with characteristic candour, was wont to relate on his ward rounds how he left a patient with a permanent biliary fistula. The patient used to send him a postcard regularly every Christmas informing him that the fistula was working quite nicely. Most of my patients selected for the filigree operation have been in the middle and latter decades of life. The general physique has often been poor to moderate, and the herniae of a type that recurrences could safely be predicted if treated along standard lines. Surgically speaking, my mouth waters when I contemplate a series of herniae in policemen. The recurrence rate on such material, using the filigree technique, should be infinitesimal.

I have in my possession a post-mortem specimen of the right inguinal canal and surrounding structures recently removed from a patient aged 80 years. This specimen demonstrates a filigree repair carried out by McGavin himself 30 years ago. If Squad. Ldr. Kinmonth would care to inspect this specimen and also some of the cases upon which I have operated I am sure that his conversion would be as speedy, dramatic, and complete as was that of St. Paul in another direction many years ago. I would, however, finish on an urgent note. This operation is well within the scope of the average competent surgeon who is conversant with the anatomy of the inguinal canal. This would-be operator should go to the trouble to observe some competent surgeon employing the technique; the haphazard employment of filigrees or their incorrect lodgment might easily lead to recurrences, and bring this magnificent method into disrepute.—I am, etc.,

W. PICKUP GREENWOOD, F.R.C.S.,
Bethnal Green Hospital (L.C.C.), London, E.2. Medical Superintendent.

Surgical Lessons of War applied to Civil Practice

SIR,—In his excellent article on adapting war surgery to civil practice Major-Gen. Ogilvie (May 5, p. 619) raises the issue of control in surgical practice. Regimentation and control may be necessary for efficiency under war and military conditions, but it is open to question whether this is necessary in civilian surgical practice. One of our national characteristics is the power of adaptation and improvisation, and already where the demand has occurred the creation of special units and centres has been established without any external pressure. Centres for cranial surgery have been established, and most reputable hospitals have their own fracture clinics, etc. If this specialization is carried further to any major degree, especially under pressure from any central authority, it will of necessity have a stultifying and inhibiting effect on the periphery.

Surgeons may be "a loose association of individuals," but they hold for the most part higher surgical qualifications and have served a long and arduous apprenticeship. In my own old teaching hospital there was the example of Sir Percy Sargent and Mr. Cyril Nitch, who made brilliant contributions to their own particular fields of specialty, and were equally at home in the field of general surgery. A surgical colleague of mine is as successful with a pneumonectomy as with an endoscopic resection of prostate. British surgery flourishes on account of its sanity, breadth of vision, and sturdy common sense. Coerced into too narrow specialization, we shall tend to become superlative technicians in a limited field, losing that clinical flair for a comprehensive grasp of the patient as a whole being.

The impact of American influence on British medicine must make itself felt. While prepared to absorb much of what is good, it seems unnecessary to adopt entirely their mode of practice with its stress on specialization. British surgery has always been in the vanguard in the past, and its general standard throughout the country, I am sure, compares favourably with and may be even better than, that practised in America and elsewhere.—I am, etc.,

Bournemouth. C. E. P. MARKBY.

Home Helps and Private Nurses

SIR,—I feel that the time has now come to relieve housewives of some of their burdens. In house after house to which one goes one finds nobody able to care for the invalid if the invalid happens to be the housewife herself. We have been promised on some uncertain date in the future a system of home helps, supplied by local authorities who will be able to do housework when required. There is now a most urgent need to start such a service.

Furthermore, in most towns the position as regards private nurses is very unsatisfactory. Before the war a nurse working on her own in a provincial town would, when she first came to the place, call on the doctors asking for their patronage.

Some years later she would vanish, and when one sent round to her address one would be told, "She left here a year ago." Much time was wasted in this way trying to find nurses; in fact most doctors in the Provinces who were at all near London used to phone up a London agency to get one. During the war the medical officer of health of almost every authority employed practically every spare nurse in the district in a first-aid post. Here in Colchester we have an excellent system whereby any private nurses coming to the town are invited to register themselves with the M.O.H., who calls on their services if we phone him up. The nurses, of course, are supposed to keep him notified as to when they are free. This system, if applied to the whole of the country, would be a tremendous advantage.

Finally, a system of hospitals throughout the country where G.P.s can attend their patients who are sick but who do not need specialized treatment is most urgently needed. The E.M.S. was set up to provide hospital services for the public, but in this area it seems to be collapsing. Our local hospital has just had to close 36 beds through lack of nurses, although there are 700 cases on the waiting list. Is the E.M.S. proposing to remain in a state of suspended animation until the National Health Service is inaugurated? For five years the Ministry of Labour has had the power to direct every girl in the kingdom, and now we find ourselves so short of nurses that we have to close down hospital beds. This seems to me a grave reflection on the capabilities of the Ministry of Labour.—I am, etc.,

Colchester. M. E. LAMPARD.

Institutional Maternity Service

SIR,—I am writing to give strong support to Dr. Laura Hutton's letter (May 5, p. 639) on the need for encouraging a home maternity service. I am in full agreement with Dr. Hutton that the happiest and often most satisfactory confinements take place in the patient's own home, but failing the provision of enough domestic service to give peace of mind to the patient I would urge the encouragement of small well-run maternity homes, of which there are many in existence, in spite of their critics. The public demand for these homes is only too evident from the difficulty of obtaining accommodation in them.

In these homes the patient can be attended by her own family practitioner, and in this case the follow-through is complete—ante-natal supervision, the confinement, the care of the nursing mother and newborn infant. To have a break in this continuity from the seventh month until a fortnight after confinement, while the patient is under the care of a doctor unknown to her in an institution, is psychologically unsound. As Dr. Hutton says, hygiene and asepsis are bought at too dear a price in cases where no difficulty is expected.

I also feel that the whole question is of psychological importance to the doctor. It is agreed that the family practitioner is of value to the community, but it is not easy to feel quite the same interest and responsibility in the life of a family when for all the major events such as confinements and operations the patient is compelled (through lack of sufficient alternative accommodation) to go to a hospital, where the general practitioner is only allowed to enter by invitation as a visitor.—I am, etc.,

St. John's Wood, N.W.8. EVELYN MACLAGAN.

Caudal Analgesia: A Rational Assessment

SIR,—As the first folk in Great Britain to have published any experiences of caudal analgesia in obstetrics (*Proc. roy. Soc. Med.*, Oct., 1944, **37**, No. 12, 680) we feel concerned that such a weighty authority in British obstetrics as Prof. F. J. Browne should have thought fit to issue a wholesale condemnation of the method (May 26, p. 746). Backed as we are by a personal experience extending over two years, we cannot allow his armchair criticism to pass unchallenged. To begin with, we question his method of attack, which consists for the most part of having combed the publications on the subject in order to catalogue all the rarest complications and presenting these as reasons against employment of the technique. Surely few procedures in medicine could stand up to so stringent a test: anaesthetics, for instance, would have been given up decades ago had the first anaesthetic deaths been the cause of professional panic.

Let us survey the subject soberly and with an attempt at clear thinking. Caudal analgesia can be subdivided into two categories—that given for a specific obstetric procedure, such as a forceps delivery or Caesarean section, and that given solely for the relief of the pain of a normal labour. The former must be compared and contrasted with other methods of securing anaesthesia for forceps or Caesarean section; the latter, on the other hand, must be compared with alternative techniques for producing adequate analgesia during parturition. All anaesthetics and analgesics for forceps delivery or Caesarean section have definite dangers and recognized complications; so has caudal analgesia. Why condemn the latter, however, and not the former? The alternative techniques for securing analgesia during normal labour also have very definite and recognized disadvantages if given in doses sufficient to maintain *adequate* relief of pain—i.e., they all tend to diminish the force of uterine contractions and slow down labour; they all tend to increase the forceps rate; most of them depress the foetal respiratory centre; and following their use there is an increased likelihood of post-partum haemorrhage. With caudal analgesia the first stage of labour remains unaffected, or, in the highly strung patient who fails to dilate readily, *it is actually speeded up* owing to the paralysis of the motor innervation of the cervix uteri—often in the most dramatic manner. Morphine and other analgesic drugs have killed far more babies than "metycaine" in the sacral canal has ever done, or is likely to do, but do we therefore condemn these drugs out of hand? Our experience is that the foetus is completely unaffected by caudal analgesia, and that cases requiring resuscitation are as few as if delivered without the exhibition of any form of analgesia. We have also found that the uterus expels the placenta in quick time—it retracts eagerly (even before an injection of ergometrine), and that haemorrhage is minimal.

On the question of the increased incidence of forceps delivery it must be admitted that Prof. Browne is on safer ground, but even here he is guilty of an over-simplification of the issue which gives a distorted impression of the facts. Had he pursued his researches into the literature a little further he would have found that all contributors (including ourselves, whom he did not quote) lay emphasis upon the disparity between the behaviour of primigravidae and multiparae upon entering the second stage under caudal analgesia. *It is the former group alone which is responsible for the increased forceps rate*; multiparae nearly all deliver themselves spontaneously. In our previous publication we concluded that caudal analgesia was not suitable for the relief of pain in the second stage in the normal primigravidae because of this increased tendency of forceps delivery. Before condemning the method in primigravidae, however, it is only fair to take into account the increased forceps rate under any form of adequate analgesia; to do otherwise is to think dishonestly or with prejudice. To overcome this disadvantage we are, at the moment, experimenting with a new technique in which caudal analgesia is discontinued during the second stage in primigravidae and an alternative substituted until the head is almost crowned, when caudal analgesia is resumed or gas-and-oxygen given; in this manner the patient has several hours of complete relief from pain and is thus enabled to cope with the second stage without having become half exhausted *en route*. Surely this is an intelligent method of overcoming the difficulty!

Limitations of space prevent all but the briefest comments on the remaining criticisms. To begin with, how many women in the second stage are able to empty their bladders spontaneously? We seem to remember that a full bladder is a well-recognized cause of delay in the second stage of labour, and, when it is, the bladder certainly cannot be voided voluntarily, even in the Garden of Eden! True, there is a small risk of infection during caudal analgesia, but there is also a risk of pneumonia from inhaling vomit during gas-and-oxygen analgesia; yet, again, no one dreams of condemning gas-and-oxygen on this account. There is some risk of infection even at the sight of injection in doing Caesarean sections under local analgesia. When cases of Caesarean section are quoted with lowered blood pressures of 60/40 for periods up to 3/4 hour we can only ask why on earth the patient was not given an injection of phoLedrine ("veritol"), or "neo-synephrin," either intravenously or intramuscularly—the latter no more difficult to give than ergometrine. Incidentally this fall in blood pressure is the only way in which the foetus can possibly be affected by caudal analgesia; and Hingson and Edwards take blood pressures every 1/4 hour as a precautionary measure. They also test the height of skin analgesia at the same time, which should never be allowed to reach higher than the umbilicus; under these conditions a fall of blood pressure is unlikely or, if present, is immediately remediable.

Prof. Browne has endeavoured to divorce the method *per se* from the skill and judgment of those administering it, an impossible procedure when discussing medical technique or treatments. He claims—quite rightly—that the "ideal analgesia in childbirth should be safe for mother and child." But how would he define the word "safe"? If by safe he means foolproof then his condemnation of caudal analgesia is justified and reasonable; but then no method of analgesia is foolproof (again, has he never heard of a foetal fatality following the use of morphine analgesia?), and to be consistent he should eschew all forms of analgesia, a policy to which we can hardly believe he would subscribe. If, however, by safe he means relatively safe then he automatically implies some degree of judgment and skill on the part of the administrator—judgment to pursue, modify, or even withhold the method according to the exigencies of the circumstances and skill to avoid its complications. It is on this very degree of skill and judgment that the safety or otherwise of the method depends; neither can be gained without personal experience, nor can any criticism carry full weight unless the critic is himself personally acquainted with the method under discussion.—We are, etc.,

Women in Labour

SIR,—This correspondence shows a healthy sign of an awakening conscience that all is far from well in the conduct of our confinements. It is somewhat startling that almost a century after the introduction of chloroform—still an excellent drug—despite the startling advances in the art of anaesthesia in recent years, the over-all standard of analgesia and anaesthesia in labour should be so pitifully low. It would even appear that a lazy acceptance of the "curse of Eve" blinds us to the suffering of a woman in labour; but not if she requires incision of an abscess or extraction of a tooth.

It is also a disturbing thought that in other aspects of midwifery there should be a similar tardy and reluctant attitude to avail ourselves of the magnificent advances in medicine generally. Wearing masks has only recently become general, if indeed it is so; *x*-ray examination is still somewhat of a novelty; *x*-ray pelvimetry a rather exceptional event. And it would be an easy task to count the number of doctors who could lay their hands quickly on a supply of plasma and a giving-set when faced with a severe P.P.H. in the home. It is high time we asked ourselves, "Why this lag in just *one* branch of our art? We are accustomed to use all the new drugs and methods of investigation in other cases; why alone in midwifery is there this stasis?"

And why do the regulations of the Central Midwives Board refuse to allow a midwife to administer nitrous oxide and air unless she is accompanied by a trained assistant nurse? The Minnett is absolutely foolproof; it just can't give too much. Our midwives have the apparatus, have been trained, but because they just can't raise another midwife or nurse to take along to the case they must not use the machine. Surely this ruling is entirely out of date? Admitted, unless the patient can afford the services of an expert in anaesthesia for the entire duration of labour the ideal method is still to be found. But a simple technique and a safe one for the midwife would be pot. bromide and chloral at the beginning, repeated if necessary; gas-and-air when the patient begins to be uncomfortable, not when she is really up against it; and at this stage a hypodermic of pethidine 100 mg. In my own practice delivery of the head is usually done under light chloroform, and for any instrumental procedure in the home it is still the ideal drug.—I am, etc.,

Oakham. GORDON PURDY.

SIR,—May I protest strongly against the wholesale condemnation of the attitude of midwives in general towards women in labour as expressed recently in your columns. Some of your correspondents have had the most unfortunate contacts during their midwifery training, and one hopes that with more experience they will get a wider field of vision and not generalize from such short observation. One must realize that there are unpleasant and inefficient individuals in every profession, but that these are not representative of the whole. To counteract the impression left on some readers by the narration of your correspondents' sad experiences I feel bound to say that in the large Edinburgh maternity hospital where I trained such unkindnesses and inefficiencies as are instanced by them would not have been tolerated for one moment, nor have I since met the attitude they exemplify in my work in midwifery institutions. I have no reason to believe that the Edinburgh attitude of compassion and courtesy—taught alike to students, doctors, and nurses—and the unforgettable kindness shown to me by the complete staff in the English hospital where I myself had two babies, are unique.

The answer to Dr. Angela Heffernan's question (May 26, p. 748): "Why do all women of the higher income levels employ doctors rather than midwives for their confinements?" is, obviously, as she will in time discover, that almost all women of whatever income level employ a midwife in any case. They realize from acquaintances if it is to be their first confinement and from experience if other than the first, that when one is in labour one craves and appreciates tremendously the comfort and reassurance of a woman and an experienced midwife, although one may engage a doctor in case an emergency beyond the scope of a midwife should arise, as well as to ensure the "whiff of chloroform" at the end.

Would it appear malicious to add, in reply to the implication that the control of the Central Midwives Board is responsible for the continuance of the suffering of "the great majority of women," that if and when midwifery does come completely under the control of the medical profession women may still suffer during labour? And not, I hasten to add, through negligence on the part of the medical profession.

To conclude, it is to be hoped that your correspondents will soon meet with the usual type of midwife, the woman whose heart is in her work, her interest including the relief of her patient's pain whether due to actual physical causes or nervous tension, and whose sympathy, understanding, and skill enable the labourer to carry through with an otherwise unendurable task.—I am, etc., JANET LACK.

SIR,—I should like to reply to some of the statements made in recent issues of the *Journal* on women in labour. Such remarks as "the callous attitude of the midwives to women in labour"; "midwives are particularly unkind to the nervous patient with a rigid os"; and "during the London 'blitz' women who remained in town had to have their babies at home as the maternity wards were closed" surely were made by someone who knows little about midwifery and less about midwives.

During the London "blitz" I was night sister in charge of fifty maternity beds, which were usually full, at one of the largest London maternity hospitals. I speak as a midwife who has been practising a number of years, including the teaching of medical students. Sedatives and gas-and-air analgesia are given routinely to all patients as necessary in the wards I have known. It is due to old-fashioned ideas and medical prejudice that midwives are not allowed to give any drug stronger than pot. brom. and chloral, or an opium pill which contains 1/10 gr. morphine, without a doctor's written prescription. We know that women in labour have to suffer at times owing to shortage of staff; enough has been said of this in the medical and lay press.

Finally, even "women of higher income levels" are left in the care of midwives as neither the hundred-guineas obstetrician nor the general practitioner has the time to wait around until "the head is on the perineum." Your correspondent who cries out for the time when all women in labour will come under control of the medical profession will have to wait a long time when one considers that more than 76% of the births in this country are dealt with by midwives.—I am, etc.

South London Hospital, S.W.4. NORA K. KELLY.

SIR,—My attention has been drawn to the correspondence in the *Journal* on the subject of women in labour. While I am in sympathy with those who deplore the neglect to maintain efficiently gas-and-air apparatus and the failure to train midwives adequately in its use, I feel that the essentials of the problem have been missed. I am convinced that a woman does not need an anaesthetic for a normal labour, but I know also how fear of the unknown can turn the uncomfortable sensations of labour into pain. Surely it is in the training of women for labour that the answer lies.

My first baby was born during the last fortnight. My labour lasted nineteen hours, and although I experienced discomfort particularly at the end of the first stage, I did not suffer anything I should describe as pain, and did not feel the need for an analgesic. The second stage I found hard work, but derived great satisfaction from being able to hasten my baby's arrival by my own efforts. My doctor advised me to use the gas-and-air apparatus for the delivery of the head to prevent my pushing too hard. I found this very helpful, not because I was experiencing pain but because by concentrating my attention on breathing deeply I was able to control the desire to push and thus avoided the alarming feeling of "splitting." I should have felt I had missed a great experience had I been unconscious when my baby arrived. I was thrilled to hold her in my arms when only half a minute old.

I am a qualified physiotherapist, and therefore had some advantage in realizing the importance of preparatory exercises, controlled breathing, and relaxation, but I have had no experience of midwifery, and consider that the most important factor in making my labour a thrilling and satisfying experience, instead of a painful operation, was my ante-natal education. This was not elaborate, and consisted of nothing more than making clear to me the processes of pregnancy and labour, and the part I would have to play in them. Any doubts and fears I had, born of my own ignorance and the harrowing tales of friends and relations, were allayed by frank answers to my questions. Doctors are, unwittingly perhaps, insulting the women they make the passive sufferers of a mystical ordeal of Nature. Give us, not the magic black-out from fear and torment, but the knowledge and the confidence to deal with them ourselves.—I am, etc.,

Southborough, Kent. JEAN SUTTON, C.S.P.

Obstetric "Specialism"

SIR,—In the Annual Report of Council, 1944–5 (*Supplement*, May 12, p. 82), it is stated that the Report on a National Maternity Service by the Royal College of Obstetricians and Gynaecologists "includes a proviso that the general practitioner who desires to undertake midwifery *must* have special experience." These self-appointed "Fellows" have an extraordinary opinion of themselves, but, their heads befogged in a cloud of self-adulation, they fail to realize that their "proviso" is a grave indictment upon their own capacity both as teachers of obstetrics and as practical obstetricians.

Carrying their advice into other spheres of medicine we should soon have our Royal Colleges of Surgeons advising that before a general practitioner would be allowed to diagnose the cause of a child's sore belly he must have special experience! Which is the more difficult, to carry out an ante-natal examination, a confinement, a post-natal examination, and decide when a case requires special hospital treatment, or to diagnose, in an infant, whether a sore belly is due to cystitis, obstruction, appendicitis, pneumonia, otitis media, or wrong feeding, and come to a decision rapidly enough to save a life?

In my opinion it would be a good thing if many of these "Fellows" spent two or three years under the supervision of a competent G.P. before being permitted to proceed to hospital for special experience and special training, and, further, a general practitioner should be a co-examiner at every obstetrical examination for ordinary degrees, higher qualifications, and under the Central Midwives' Board. I wonder how many self-styled obstetric specialists know anything of normal labour. How many of them, since their student days, have watched a maternity case from beginning to end or seen hundreds of such cases as I and many of my colleagues have? We would have our women less fearful of labour than they are to-day, and less interference of labour carried on by the methods devised by God, if many of our obstetric specialists knew more about normal labour. Women of to-day would face labour as their mothers did, without fear, and full of joyful anticipation, and little, if any, post-natal suffering. What is this "special experience"? Possibly watching a variety of specialists carrying out a variety of episiotomies; possibly watching a variety of women in labour being subjected to a variety of anaesthetics—general, local, intravenous, and intrathecal—and a variety of stillborn infants make their appearance into the world; possibly viewing a variety of means of inducing premature labour with callous indifference for infant life, for conditions quite capable of being treated by simple common-sense medical means. One would, of course, view a variety of Caesarean sections, and picture on occasion the puzzled glow on the specialist's countenance as he wondered whether there was an ovarian cyst lurking in the background, the cold sweat pouring off his brow at the thought that he had removed the baby before the cyst.

Yes, there is a place for the obstetric specialist, a very vital place, though he makes just as many errors of diagnosis and judgment as the general practitioner, and he would be a fool if he did not; but there is no place for this driving women into ante-natal hysterics, irrational operative procedures, and breaking down the very foundations of home life by this constant specialist barking; this driving women to hospital, and a forgetting that midwifery, if it calls for our best judgment and common sense, is that department of medicine where diagnosis is easiest, and we can help our women in the vast majority of cases, by the simplest means in the world.—I am, etc.,

Tain. E. K. MACKENZIE.

Adrenalectomy in Paranoid Psychosis

SIR,—The further development of the case of psychosis treated by adrenalectomy, reported by Dr. Clifford Allen and Mr. L. R. Broster in the *Journal* of May 19 (p. 696), may be of interest.

The patient's physical condition has hardly been influenced by the operation. Though her voice has become higher her body up to the waist is still covered with thick and coarse hair, she has a vertical distribution of pubic hair, and has to shave her face frequently. During the first few months after adrenalectomy her thinking was retarded, she was easily tired, and complained of inability to concentrate and of lack of initiative. She was greatly distressed about this condition, and wondered whether she would ever get well. She found it difficult and embarrassing to meet people as she could not converse with them. She gained 7 lb. in weight. From the 4th to the 7th month after the operation she was given 2.5-5 mg. benzedrine and, for periods of 3 to 4 weeks, thyroid gr. 2 daily. Gradually she lost her excessive weight, became more self-confident and sociable, and was able to resume normal household and social activities. Eventually she took up regular duties at a Forces' canteen.

With regard to her mental state the operation has proved a complete success so far. She has lost all psychotic symptoms and homosexual leanings, her habits have become feminine again, and she dresses with care and smokes little. In addition, the claustrophobia, the facial tic, and the occasional stammering which preceded the psychosis for at least seven years have disappeared. She is now three months pregnant and looks forward to having a child.—I am, etc.,

Manchester. LEO WISLICKI.

Tuberculosis of the Lower Lobe

SIR,—I am grateful to Dr. George Luntz for calling attention in his letter (May 26, p. 747) to a passage in my article on the above subject in which I referred to the use of pneumoperitoneum. I agree with Dr. Luntz and the authors he quotes that diaphragmatic paralysis is generally more efficient with lesions of the lower and upper lobe than in the middle lobe, and I regret that the disputed passage gave the impression, which I did not mean to convey, that phrenic paralysis followed by pneumoperitoneum was *particularly* valuable in mid- and lower-lobe lesions.

At the same time I would like to point out that my article was dealing with the lower lobe, and the passing reference to middle-lobe cavities was not intended to be taken as a definitive conclusion. I can only say that though the number of middle-lobe cavities I have so far treated by phrenic paralysis and pneumoperitoneum is comparatively few, this treatment has been successful in a sufficient number of cases to warrant its trial when artificial pneumothorax fails.—I am, etc.,

Essex County Hospital, Braintree. R. C. Cohen, M.D.

Shall We Nationalize Medicine?

Sir,—The letter from Dr. Dakin (May 19, p. 715) is, in my opinion, one of the most sensible of the numerous letters written on the subject of a national medical service. Dr. Dakin rightly stresses the importance of conducting professional work away from the home. The difficulty of obtaining adequate domestic help before the war was acute and may even be more so after the war. The shortage of domestic workers may render practice from health centres almost essential if doctors and their wives, especially the latter, are to lead lives of reasonable comfort free from intolerable drudgery.

Whereas it would be undesirable to curb a doctor's potentialities by unduly restricting the size of his practice, there is obviously a limit to the number of patients to whom he can give adequate attention, this number depending on the type of practice, urban or rural. Further, if the whole population is to be insured the option suggested of permitting patients to make their own private arrangements for medical treatment matters little to the doctor. What certainly does matter is the capitation fee, for if this is adequate it may well be that in the average practice the practitioner may prefer all his patients on his insured list. With a basic capitation fee of, say, £1 a practitioner would probably obtain a greater net income than from a practice composed partly of private patients with expenses in connexion with drugs, dispensing, etc.

I agree with Dr. Dakin that it is lamentable that conditions in practice nowadays are such that many doctors, especially the single-handed ones, have to work unreasonable hours making undue demands on their physical and mental powers. This pernicious state of affairs could be rectified by practice from health centres, in which more or less regular hours of work could be arranged, with rotas for night work and holidays for all. Those doctors referred to by Dr. Dakin who feel they are not true to their calling unless always on duty could gratify their desires to the full, for in each centre there would be a fair proportion of doctors who like, and feel entitled to, recreation at the end of an exacting working day. Under a national medical service with practice divested of much of its competitive character, it would be interesting to observe whether the zest for work and day and night devotion to duty of some doctors would continue unabated, or would decline with the curtailment of income which would occur in some instances.—I am, etc.,

Hornsea. L. French.

Flour in the Loaf

Sir,—Sir Ernest Graham-Little, having been shown to be completely wrong in his statement that the germ of imported wheat is removed in the country of origin before importation to this country, now brings forward another suggestion in his letter (May 26, p. 750). This suggestion is that the majority of the cereals imported is in the form of white flour (germ removed), so that the amount of germ imported via wheat is small. Again, Sir Ernest Graham-Little is, as is so often the case, entirely wrong as to his facts. The majority of imported cereals is in the form of wheat, from which, as he now knows, the germ has not been removed. This is clearly seen from the fact that the present miller's grist in this country for the manufacture of flour for bread-making is approximately 40% English wheat and 60% imported wheat (mainly Manitoba). The imported flour (germ removed) added is less than 20%, so that, contrary to what Sir Ernest Graham-Little states, there is about three times as much wheat imported as flour. The correctness of these statements can be easily confirmed by inquiry at the Ministry of Food. It is unfortunate that Sir Ernest Graham-Little does not trouble to get his facts correct and gives publicity to statements which are incorrect and hence misleading.

I purposely refrained from entering into controversial matters and have merely restricted myself to showing that statements, on which certain arguments are based, are incorrect in fact. Hence I do not propose to carry on this correspondence. However, perhaps I might be permitted to make the following observations.

Sir Ernest Graham-Little says (May 26, p. 750): "I think Dr. Kent-Jones is likely to hear from the makers of biscuits whose product is thus revealed as consisting, like the pre-war bread, almost entirely of starch!" My experience of biscuit manufacturers is that the majority of them are not likely to be at all perturbed by my statement of fact concerning the destruction of B_1 in biscuits, but they will know that the claim that biscuits merely contain starch is another example of Sir Ernest Graham-Little's misstatements. Biscuits contain, besides starch, protein and fats and other nutrients.

Sir Ernest Graham-Little further states: "It may profitably be noted that Russian soldiers have won their resounding victories on a diet mainly composed of whole-grain bread." This interesting observation can scarcely be considered as a serious argument. If it is, then one must also remember the great victories gained by the American soldiers who received enriched white bread. Also, readers may like to remember that the youth of Great Britain, bred on white bread, whatever its defects, fought and won two major wars in the last twenty-five years.—I am, etc.,

Ealing, W.5. D. W. Kent-Jones.

Sir,—Sir Ernest Graham-Little, having been shown to be factually inaccurate on every major point he attempted to make, now retires behind a smokescreen (May 26, p. 750). His argument now is "that it is against the interests of the public . . . to divert one penny-weight [of wheat germ] to any purpose other than the provision of the most nutritive national loaf that science can devise." The only purpose for which germ (in the form of milling offals) can be diverted from the national loaf is for stock feeding purposes, a fact of which Sir Ernest Graham-Little is well aware. The rest of his letter is therefore irrelevant to the point under discussion. Careful scrutiny reveals, indeed, that he does not—because he cannot—contradict my statement (supported as it is by numerous Hansard references) that "not one flake or particle of Bemax is derived from flour either intended to be or actually used for bread-making." This is my point and on that I rest.—I am, etc.,

H. C. H. Graves,
Chairman and Managing Director,
Vitamins, Limited.

London, W.6.

⁂ This correspondence is now closed.—Ed., *B.M.J.*

Civilian Jobs for Medical "Other Ranks"

Sir,—Many medical practitioners must have had the experience during these war years of working with Regimental and Medical Corps N.C.O.s and orderlies, and found them, if "unskilled," most efficient. Are these men now to be returned to their forges, shops, and ploughs, and so lose the training they have acquired and also be a complete loss to our profession, or can we offer them reasonable employment at reasonable wages? Could some of them not administer our smaller hospitals, or if "rehabilitation" is to increase vastly is this not the man-power—and many being ex-bandsmen have an additional musical knowledge—which we must seize? If any organization exists for the absorption of these people can it not be given wider publicity so that those of us still in a position to direct may be able to give the correct directions?—I am, etc.,

Helensburg, Dumbartonshire. John McD. Glennie, M.B.

The Services

The following appointments and award have been made in recognition of gallant and distinguished services in Italy:

O.B.E. (Military Division).—Cols. K. A. Hunter, G. A. Sinclair, and H. G. Young, D.S.O., M.C.; Lieut.-Col. W. L. Coke; and Major D. A. Young, R.C.A.M.C.

M.C.—Major (Acting) D. W. McCullough, R.C.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Missing, presumed killed.—Surg. Lieut.-Cmdr. Ronald Grant Dingwall, O.B.E., R.N.

Obituary

CARLTON OLDFIELD, M.D., F.R.C.P., F.R.C.S.

We regret to announce that Mr. Carlton Oldfield, the well-known Leeds consultant and former professor of obstetrics and gynaecology in the University of Leeds, died on May 27 at his home, Moor House, Harewood, aged 74. Almost the whole of his professional life was spent in the Leeds district, with which his family has had a long association.

A student of the Leeds School of Medicine, Carlton Oldfield came to London to take the English Conjoint Diplomas in 1893, graduated M.B., B.S.Lond. two years later, and proceeded M.D. in 1905 after holding a succession of junior posts. He became a Fellow of the Royal College of Surgeons of England in 1909 and was elected a Fellow of the Royal College of Physicians of London in 1928. Before his appointment to the staff of the General Infirmary at Leeds as honorary gynaecological surgeon he had been surgeon to the Leeds Maternity Hospital and to the Leeds Hospital for Women, and he was also visiting gynaecologist to the Batley and District Hospital, the Dewsbury General Infirmary, the Wakefield Clayton Hospital, the Skipton and District Hospital, and the Coronation Cottage Hospital at Ilkley. In 1919 he succeeded the late Prof. J. B. Hellier in the chair of obstetrics and gynaecology at Leeds University and held the professorship until 1932. He retired from active practice in 1939. He had examined for some years in his subject at the University of Oxford, and was a past president of the North of England Obstetrical and Gynaecological Society. In 1929 he revised Herman's standard work *Difficult Labour* for its seventh edition; he wrote the article on septic infections for Eden and Lockyer's *New System of Gynaecology*, and contributed papers to this and other journals.

Mr. Oldfield joined the British Medical Association in 1897 and was honorary secretary of the Section of Gynaecology and Obstetrics at the Annual Meeting held in London in 1910; he was also for many years a member of the Leeds and West Riding Medico-Chirurgical Society and a Fellow of the Royal Society of Medicine. Throughout his career as teacher and consultant he took a warm interest in the advancement of younger members of the hospital staff and in the promotion of better welfare and working conditions for the nurses. He leaves a widow, two sons, and two daughters; one son is Major Michael Oldfield, F.R.C.S., now serving abroad with the R.A.M.C., who in civilian life is assistant surgeon to the General Infirmary at Leeds.

JOHN DICK, M.B., D.P.H.

J. J. J. sends the following appreciation of the life and work of Dr. John Dick, medical superintendent of St. James's Hospital, Leeds, from 1926 to 1945.

He joined the staff of Firvale—now the City General Hospital—in Sheffield, where, under the efficient tutelage of Dr. James Clark, its distinguished medical superintendent, also a Scot, he learned not only how to apply the knowledge he had acquired in Edinburgh but also how to administer a large hospital, and in a comparatively short time he was promoted to the post of deputy medical superintendent. In 1926 Dr. James Allan, the venerable and well-loved medical superintendent of St. James's Hospital in Leeds, retired, and out of a large number of applicants Dr. Dick was chosen to fill the vacancy. He was then only 32 years of age, which was considered young for the holder of such an onerous post. For the first eight years of his service in Leeds he was an officer of the Public Assistance Committee, and it was not until 1934, when the three hospitals under the control of that committee—St. James's, St. Mary's, and St. George's—under powers conferred by the Local Government Act of 1929, were appropriated as part of the general hospital service of the city, that he was transferred and became a member of the staff of the Public Health Department.

From the outset of his public life his desire was to see St. James's Hospital in the first rank not alone of municipal general hospitals but of all, including the most up-to-date voluntary hospitals, and towards this goal he strove with might and main. At the time of his death the goal was in sight, and he had the satisfaction of seeing the first-fruits of his labours beginning to appear. He reorganized the medical and nursing staffs, modernized and re-equipped the wards, built new operating theatres, pathological, radiological, and physiotherapy blocks, and installed new *x*-ray and electrical apparatus. For the nurses, whose comfort and welfare lay very close to his heart, he provided extended and improved accommodation for living, dining, and recreation, and to assist them in their studies and preparation for their examinations a complete and up-to-date school of instruction. What he did for St. James's he did in a minor degree for the other hospitals under his care. At St. Mary's Infirmary in particular out of a block that had become obsolete he fashioned and equipped on modern lines a maternity unit. Acutely alive to the social implications of disease, he was instrumental in establishing an almoner's department with a staff of trained and qualified almoners to serve all the hospitals in the group.

Perhaps his greatest work, however, lay in his linking up of St. James's Hospital with the General Infirmary at Leeds and the other voluntary hospitals in the city. With skill and tact—for at the inception of the idea there was suspicion on both sides—he overcame opposition and succeeded in bringing the two systems together and interweaving them in such a way as to form a useful and valuable combination. In furtherance of this policy of friendly co-operation he built up a staff of visiting specialists who, in the main, were the same as those attached to the General Infirmary at Leeds and teaching school, thus taking the first step towards the identification of St. James's Hospital with the Leeds School of Medicine in the teaching of undergraduates. That St. James's Hospital should one day become a teaching hospital and enter the ambit of the Leeds University was one of his dreams which may be nearer fulfilment than even he at the time of his death realized. The formation of a Joint Hospitals Advisory Committee, with which he was intimately associated, was another step in the same direction.

The last, and not the least important, of his achievements was the taking over from the Public Assistance Committee in April, 1944, of the buildings known as North Lodge, which adjoin St. James's Hospital, and their appropriation for hospital purposes, thus raising the number of beds in the combined hospitals (North to South) to 1,800, which makes it the largest general hospital in England. Plans for adaptation of the newly acquired buildings have been approved and part of the work has been carried out, but the completion of the scheme will occupy many months. Though the author of these plans and proposals will not see them come to fruition, the hospital when complete will be another monument to his foresight and enterprise. This addition to the territory under his control made it necessary to share the responsibility for the management of the hospitals with another medical superintendent. The hospitals were split into two groups—an inner, consisting of St. James's Hospital (North and South), and an outer, of the other hospitals, now increased to three. While retaining the medical superintendency of the inner group he continued to exercise a general supervision over the whole, under the title of Medical Director of General Municipal Hospitals. The burden resting upon his shoulders, at no time light, was greatly enhanced by the war. He was called upon not only to arrange for the protection of the hospitals from air attack but also to ensure their proper staffing and maintenance under the most trying conditions. St. James's became an E.M.S. Hospital and was adapted to deal with civilian as well as military casualties, while within it there was incorporated a special unit for injuries of the face and jaw, the only one of its kind in the region. For a short period at the beginning of the war he was lent to the Ministry of Health to help in the planning and development of a hospital system for the North-East region.

Nineteen years in the normal span of human life and experience is not a long time, but when those years are packed with high endeavour and great achievement they make history. What Dr. Dick wrought for the advancement of medical science during the nineteen years of his superintendency will form an outstanding chapter in the history of the hospital service of Leeds. In his home life he was fortunate too. If he had given much to St. James's Hospital it did not deal niggardly with him, for it gave him a wife. In Mrs. Dick he had one who not only loved and sympathized but who knew and understood the weight of responsibility he had to carry, and was therefore able to render the help he so much needed, especially during the anxious days of the early part of the war. In the turmoil of life his home was an oasis where he found refreshment, encouragement, and hope. When death came it found him as he would have wished it to find him, at his post surrounded by familiar scenes and sounds and faces in the midst of the institution he knew and loved so well and for which he had laboured so assiduously, so faithfully, and so long.

Dr. THOMAS DIXON TODD died at Wath-on-Dearne on May 23. Before studying medicine he had been a schoolmaster, and for eleven years was senior languages master at Mansfield Grammar School. He qualified M.B., B.S.Durham in 1939, and after a period at Darlington and Ollerton settled in practice at Wath-on-Dearne four years ago. While of a retiring disposition, those who were privileged with his confidence and friendship realized his innate courage clothed with gentleness, his inherent steadfastness concealed under a never-failing courtesy and regard for others. He was held in high esteem by his colleagues and patients, and his untimely death is a grievous loss to the district. Deep sympathy is extended to his nearest and dearest.—I. C.

Universities and Colleges

UNIVERSITY OF OXFORD

In Convocation on May 29 it was resolved to confer the honorary degree of D.Sc. on Hubert Maitland Turnbull, M.D., F.R.S., F.R.C.P., Professor of Morbid Anatomy in the University of London.

Charles Garrett Phillips, B.M., B.Ch., has been elected to an official Fellowship as Lecturer in Physiology at Trinity College. Miss Celia K. Westropp, D.M., has been appointed to a Tutorship in Natural Science at Lady Margaret Hall.

UNIVERSITY OF LONDON

London School of Hygiene and Tropical Medicine

At the end of the present session Prof. Major Greenwood, F.R.S., retires from the Chair of Epidemiology and Vital Statistics at the London School of Hygiene and Tropical Medicine under the age limit. Owing to a change in the distribution of teaching and steady increase in the volume of research work and teaching within the field of medical statistics, the title of the chair has been changed to that of Medical Statistics. Mr. A. Bradford Hill, D.Sc., Ph.D., Reader in Medical Statistics in the University since 1933, has been appointed to fill the vacancy. The Senate has conferred upon the retiring professor the title of Professor Emeritus in Epidemiology and Vital Statistics in the University of London.

UNIVERSITY OF MANCHESTER

At the meeting of the University Court on May 30 Sir John Stopford, the Vice-Chancellor, gave a general survey, in which he said that by December the University would be virtually "unwound" except for certain controls with regard to the admission of students and the completed return of the teaching staff. One of the major problems for a long time ahead would be the finding of new members of staff. Limited accommodation was a secondary difficulty; they were faced by a considerable increase of students to meet the urgent national demand for teachers, doctors, and dentists. Three new chairs had been established, including one in medicine and one in industrial health; the former would be whole-time, as had been contemplated before the war; and the latter was, under Dr. R. E. Lane, the first full professorial department in the subject in Great Britain. The Vice-Chancellor was hopeful that by next September the University would have the financial support needed to start a full professorial department of child health.

UNIVERSITY OF EDINBURGH

Charles Cameron, M.D.Glas., F.R.F.P.S., has been appointed to the Chair of Tuberculosis in the University in succession to the late Sir Robert Philip. Dr. Cameron has been medical superintendent of the South-East Counties of Scotland Sanatorium, East Fortune, for the past 22 years, and took charge of the tuberculosis department at Bangour Hospital under the Emergency Medical Service. He is a past president of the Tuberculosis Society of Scotland.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

The Croonian Lectures, which were unavoidably postponed, will now be given at the College by Surg. Capt. Macdonald Critchley on Tuesday and Thursday, July 10 and 12, at 4.30 p.m. His subject is "Problems of Naval Warfare under Climatic Extremes."

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Sir Hugh Devine's Honorary Fellowship

The President, Sir Alfred Webb-Johnson, Bt., has received from Sir Alan Newton, President of the Royal Australasian College of Surgeons, a letter dated March 19, 1945, in confirmation of a personal message by air mail, recording that H.R.H. the Duke of Gloucester had admitted Sir Hugh Devine as an Honorary Fellow of the Royal College of Surgeons of England at Government House, Melbourne, on Feb. 23. Sir Alan Newton enclosed a copy of his address to the Governor-General of Australia and also of His Royal Highness's reply, part of which was spoken directly to Sir Hugh Devine, a founder and Past-President of the Royal Australasian College of Surgeons, as follows: "The value of your work in the advancement of surgery has been most deeply appreciated and your wise and cautious guidance has been the means of saving many lives during the war—so much so that your counsels have come to be spoken of as the 'Devine Precepts.' Australian surgeons have made most remarkable and stimulating contributions to the science and art of surgery, and none have been more fruitful than your own. It is therefore a special pleasure to me to bring you greetings from your colleagues of the Royal College of Surgeons of England, of which I am myself an Honorary Fellow, and to present you with your Diploma. In the name of the College and by the authority of the President and Council I admit you as a Fellow of the Royal College of Surgeons of England—*Honoris Causa.*" The following is a quotation from Sir Alan Newton's letter to Sir Alfred Webb-Johnson: "May I take this opportunity of emphasizing the fact that my reference to our debt to the Royal College of Surgeons of England expressed the feelings of all the Fellows of the Royal Australasian College of Surgeons. It is our intention to send you a gift of money to help you to repair the damage to the College in Lincoln's Inn Fields and we intend to obtain for you such anatomical and pathological specimens as may be of value to you. Either I or my successor who will be appointed in May of this year will write to you further about these intentions. It was a very great pleasure to us that Surg. Capt. Lambert Rogers was able to be present on this occasion and we look forward to seeing him again at a College meeting to be held in Melbourne in May. There will be a public meeting in the Wilson Hall, where you will remember giving your Syme Oration with such success, and I have arranged for Lambert Rogers to speak at this meeting as a member of your Council. I know that he will make a public reference to the close association between the two Colleges. I trust that you and your Council will approve of the way in which the ceremony was carried out in Australia, and assure you that Devine, and all of us who are his colleagues, are deeply appreciative of the great honour you have done to Australasian Surgery in conferring an Honorary Fellowship upon him."

Medical Notes in Parliament

Artificial Insemination in Animals

Mr. Tom Williams moved on May 17 the second reading of the Agriculture (Artificial Insemination) Bill. He reminded the House that Section 17 of the Agriculture (Miscellaneous Provisions) Act, 1943, had endorsed the principle of controlled development of artificial insemination. Problems still required investigation, such as the keeping quality of semen, insemination methods, and technique, which were unsuitable for investigation at a commercial centre. In Clause 1 of the new Bill the Minister of Agriculture and the Secretary for Scotland sought power to set up artificial insemination centres where research and experiments could be carried on. These centres would also provide a limited service to farmers in the neighbourhood. The clause would also allow financial assistance to be given to organizations or persons undertaking approved investigations. The clause would enable the Ministry to carry out investigations in the case of all animals, including poultry, but not human beings. In England and Wales the Milk Marketing Board were leading in the establishment of artificial insemination centres. The method was going to be of more use for dairy herds than for beef herds.

Mr. Wootton-Davies said the process had been of more use for horses than for cattle. He himself sent to South America semen from his rams. But the House should not approve this method without consideration. The mating of animals was not just like mixing an acid with an alkali. Mr. Price doubted whether the country had stock which could be used with certainty for improving the quality of dairy cattle. Mr. Chapman, replying for the Government, said the two Ministries concerned had arranged, in printed regulations, a thorough control of the practice of artificial insemination.

The Bill was read a second time.

Pneumoconiosis and the Mines Inspectorate

Moving on May 29 a motion to approve the Coal Charges (Amendment) Order, Major Lloyd George said he had many complaints of the food for miners. It was disappointing to find so small a percentage of the mineworkers taking full advantage of the extension of canteen facilities. He wished to say a word about health services. Rehabilitation centres had been greatly increased during the last four years with the aid of the Welfare Commission. With regard to pneumoconiosis which affected miners most in West Wales and South Wales the Ministry of Fuel and Power had been able to increase its staff of doctors, with great difficulty, to reduce the waiting-list It was to have a research centre. There, he hoped, a cure would be found for this disease about which little was known at present. The waiting-list was at one time 3,000. There had been some change since increased medical staff were obtained He hoped to get rid of the arrears in nine to twelve months

Dr. Summerskill asked how many specialists there were for pneumoconiosis. Major Lloyd George said there were four panels. His recollection was that a doctor who was a specialis in the disease was at the head of each. It was difficult to get the right men. He was told that one could not regard the ordinary tuberculosis specialist as having any real knowledge of this extraordinary disease. He hoped after the Japanese war to have the services of many more who had experience of the disease, and also that as a result of putting up a research centre to have a proper clinic and contacts with other countries where the same thing was found in different forms.

Dr. MORGAN asked what steps were being taken to train either young medical men or older men who were experts in respiratory diseases to enable them to get the requisite knowledge of the disease. Major LLOYD GEORGE said there was a great shortage of medical men of all categories. The Ministry had increased the number of panels available. He was anxious to clear off the waiting-list. Dr. MORGAN said that when the Ministry was formed there were about nine medical inspectors for the different mining districts. He did not know the present number. Did their work deal purely with safety arrangements? Had it anything to do with ventilation or humidity? Could the House get any detailed health statistics for the industry as a whole? There were now three teaching schools with professorships of industrial medicine, but no lectureships in London connected with it. Had the Minister a Medical Appointments Board? How did he recruit and train these inspectors? Medical men did not know. What arrangements were being made for the appointment of a Silicosis Board? There should be intensive training, because the more machinery put into the mines the more dust and cases of disease there would be. The Minister's medical inspectors should ensure that when accidents happened the roads were cleared so that the badly injured workman could be got out of the mine easily.

The "Minister of Health"

Mr. CHURCHILL remarked on May 30 that he never liked the change from "President of the Local Government Board" to "Minister of Health," but thought it would be a great mistake to make another change now.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* large increases were reported in the incidence of measles, whooping-cough, acute pneumonia, dysentery, and diphtheria, which rose by 1,714, 269, 101, 91, and 85 cases respectively. Seven cases of typhus fever were notified.

Whooping-cough increased in most areas of the country, the largest rises over last week's totals being Yorks West Riding 37, Lancashire 41, London 29. Diphtheria was most prevalent in the North; the chief local rises over last week's totals were: Northumberland 16, Staffordshire 13, Durham 12, Derbyshire 12, Worcestershire 11. There was a general rise in measles, except in the north. The largest increases were in the counties surrounding London, the increases over last week being as follows: Surrey 233, Kent 163, Buckinghamshire 106, Bedfordshire 102, Berkshire 102, Hertfordshire 99. Yorks West Riding reported a fall of 107 in incidence.

The rise in dysentery was due mainly to increases in existing outbreaks. The largest returns were Lancashire 56, Yorks West Riding 50, Staffordshire 46, London 31, Gloucestershire 24, Middlesex 22, Warwickshire 22, Essex 14, Pembrokeshire 14, Hertfordshire 12, Glamorganshire 11, Kent 10, Southampton 10, Lincolnshire 10.

In *Scotland* notifications exceeded last week's totals as follows: measles 248, whooping-cough 56, scarlet fever 16, diphtheria 9. The increase in measles and whooping-cough was mainly in Glasgow. There was one case of typhus fever.

In *Eire* the notifications of whooping-cough increased by 42, and of measles by 10, but there were 10 fewer cases of diphtheria. The rise in diarrhoea and enteritis—26—was due to an outbreak in Dublin C.B., where 25 of the 36 cases were reported.

In *Northern Ireland* there were 16 more cases of whooping-cough than last week.

Typhus in Paris

Sixty-six cases of typhus have been reported in Paris, 64 of the patients being former prisoners or deportees. In anticipation of returning prisoners spreading infection Shaef ordered all men in rear areas to be inoculated or reinoculated against typhus some weeks ago.

Week Ending May 26

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,295, whooping-cough 855, diphtheria 396, measles 11,408, acute pneumonia 487, cerebrospinal fever 50, dysentery 374, paratyphoid 3, typhoid 8. The cases of typhus during the past weeks have occurred among returning prisoners of war. Anyone entering Britain from the Continent has to undergo a rigorous test for typhus, and special precautions have been taken in case of an outbreak.

No. 20

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended May 19.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

H.R.H. the Princess Elizabeth will present prizes and certificates to students of the London (Royal Free Hospital) School of Medicine for Women on Thursday, June 21, at 3 p.m. in the Great Hall, British Medical Association House, Tavistock Square.

The forty-sixth annual meeting of the Association of Port Health Authorities of the British Isles is to be held in the City Hall, Cardiff, on June 14 and 15. There will be a tour of the docks and visits to the Royal Hamadryad Seamen's Hospital and the Llandough (Cardiff Municipal General) Hospital. Mr. D. G. Hoppins will read a paper on "The Port of Cardiff in Wartime," Mr. J. W. Wellwood on "The State and the Welfare of Merchant Seamen in Ports," and Col. P. G. Stock on "The International Sanitary Convention of 1944."

On Friday, June 15, at 4.30 p.m., a coloured film showing movements of the brain in concussion, etc., will be demonstrated by Lieut. Robert Pudenz, U.S.M.C., at the Royal Society of Medicine. By means of high-speed cinema-photography a monkey's brain has been investigated through a plastic calvarium. Lieut.-Gen. Sir Alexander Hood will preside.

The Queen's Institute of District Nursing Secretaries Association has arranged a National Conference of District Nursing at 10.45 a.m. on Saturday, June 16, in Crane Theatre, Hanover Street, Liverpool. The speakers include Sir Weldon Dalrymple-Champneys, D.M., Miss J. M. Calder, Miss E. J. Merry, and Dr. O. R. Belcher.

The East India Association (3, Victoria Street, S.W.1) announces that on Tuesday, June 19, at 2.30 p.m., at the Rooms of the Royal Society, Burlington House, Piccadilly, brief addresses on "Indian Health Problems: Some Recent Voluntary Efforts", will be given by Lieut.-Col. I. M. Orr, M.D., R.A.M.C.(ret.), Mr. Howard Somervell, F.R.C.S., and the Rev. J. C. McGilvray, bursar of Vellore Christian Medical College.

Lord Moran, P.R.C.P., will deliver the Cavendish Lecture before the West London Medico-Chirurgical Society at Kensington Town Hall on Tuesday, June 19, at 8.30 p.m. His subject is "The Art of Command."

The annual meeting of the Members of the Royal Medical Benevolent Fund will be held at 3.30 p.m. on Wednesday, June 20, at the Medical Society of London, 11, Chandos Street, W.1, when the financial statement for 1944 will be presented and the officers, committee, and honorary auditors elected for the current year.

A clinical meeting of the Middlesex County Medical Society will be held at Harefield County Hospital on Wednesday, June 20, at 3 p.m. Clinical demonstrations will be followed by a short paper by Drs. E. Nassau and P. F. Kennish entitled "An Analysis of Cases Admitted for Treatment from the Mass Radiographic Unit."

A special meeting of Fellows of the Royal Society of Medicine was held on May 24, at which eight elections were made to the Honorary Fellowship of the Society, the highest honour which the Society can bestow. The British recipients were Surgeon Vice-Admiral Sir Sheldon Dudley, Lieut.-General Sir Alexander Hood, Air Marshal Sir Harold Whittingham, and Sir Francis Fraser, respectively Directors-General of the Medical Services of the Royal Navy, the Army, and the Royal Air Force, and the Emergency Medical Service. The four foreign recipients were Colonel V. L. Gallemaerts, Colonel-General Smirnov, Dr. Karl Evang, and Colonel Frantisek Langer, representatives respectively of the medical services of Belgium, Russia, Norway, and Czechoslovakia. At the same meeting it was announced that the 1944–5 award of the Gold Medal of the Society had been made to Brigadier Sir Lionel Whitby. To the presidency of the Society Surgeon Rear-Admiral G. Gordon-Taylor was re-elected for a further term.

Princess Arthur of Connaught was the chief guest at a luncheon party on May 30 at the Mansion House in support of an appeal for funds to rebuild and equip the Marie Curie Hospital for cancer and allied diseases. Another guest was Lieut. Eve Curie, daughter of Mme Curie. The Lord Mayor presided. The main building of the hospital in Fitzjohn's Avenue, N.W., was totally destroyed by enemy action, and the x-ray wing was seriously damaged.

The difficulty of ridding clothing, etc., of lice and their eggs by baking the articles at a temperature of 212° F. for twenty minutes is that clothes—woollen articles particularly—are good insulators. The Industrial Gas Centres of the Gas, Light and Coke Company and the South Metropolitan Gas Company have provided a means of heating a disinfestation oven—a brick chamber open at each end, through which a conveyor carrying frames for the clothing and blankets is passed. Information on the method of heating, safety devices; and the tests of efficiency of the oven in killing lice and their eggs carried out by Dr. Busvine are contained in a memorandum received from Gas Industry House, London, S.W.1.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Disappearance of Psoriasis in Pregnancy

Q.—*A woman aged 22 had psoriasis in head, neck, elbows, and knees. Various treatments improved the condition, but it always returned. She got married and became pregnant; the rash disappeared at once, but reappeared soon after the baby was born. She has now had three confinements, and the same disappearance and return of the rash has happened each time. Would treatment with the male hormone be of any use? Possibly someone has already had similar cases, and treated them with a hormone.*

A.—Disappearance of the rash of psoriasis during pregnancy is met with occasionally. As it is not a constant phenomenon and as the reverse may occur, the interpretation in the light of present knowledge is difficult or impossible, and affords no precise indication for hormonal treatment.

Humidity of Temperature of Inspired Air

Q.—*In the B.M.J. of March 10, in reply to a question on air conditions and chronic bronchitis, it is said that the bronchial mucous membrane is atrophic and therefore unable to deal satisfactorily with changes of humidity and temperature. Is it ever the function of the bronchial mucous membrane, even when healthy, to affect the humidity and temperature of inspired air? Is this not the function of the mucous membrane of the nose, where the turbinate bones, acting like baffles, enforce a more prolonged contact of the incoming air with warm and moist mucous membrane? In my experience chronic bronchitics are unconscious and unwitting mouth-breathers in that automatically, before each act of coughing, air is inspired through the mouth, although the nose itself is free and unblocked. Automatically the nose, the natural air-conditioning plant of the body, is by-passed. Chronic bronchitics should, therefore, be taught to close the mouth at the end of each act of coughing and inhale slowly through the nose.*

A.—Normally, with quiet breathing, the nasal mucosa serves to warm and moisten the inspired air; but when the ventilation volume is increased, as during exercise, air is taken in also through the mouth and it is likely that part of the moistening and warming occurs in the lower respiratory passages. Even the atrophic mucosa must be warm and moist and able to exert some effect on the inspired air. But in doing so the mucosa loses water and heat, and it is unlikely that the atrophic mucosa can replace them as rapidly as the normal mucosa can. During coughing, as your correspondent says, air is likely to be inspired through the mouth. It is the drying of the atrophic mucosa and consequent irritation which should be avoided. Nose breathing should help to prevent this, but whether slow inhalation through the nose is always possible when coughing is reflexly induced is open to question. However, there seems to be no harm in trying.

Giant Urticaria

Q.—*A young farmer suffers from chronic urticaria; his eyelids, lips, and tongue swell, and wheals have appeared over his body, the largest being the size of a dinner-plate. Attacks occur most often in the evening. During the day he is usually free. No treatment is of any avail. What should be done?*

A.—Chronic urticaria, with or without "giant" lesions, may be related to many factors, among which focal infection, food allergy, or a psychological disorder may be the determining causes. It is remarkable how the removal of an infected tooth or the elimination of some unsuspected article of food may sometimes produce complete relief. As all physical measures of treatment have failed, psychotherapy should be considered. The possibility of oedema of the glottis should be kept in mind: severe attacks can be often reduced by 5 minims of adrenaline injected hypodermically and repeated every 15 minutes up to a reasonable limit.

Chronic Sinusitis and Swimming

Q.—*Is it safe to permit swimming in the case of a sufferer from chronic maxillary sinusitis? (I take it diving is absolutely contra-indicated.)*

A.—It should be safe to permit side and breast stroke; but such racing strokes as trudgeon crawl would be as risky as diving. In a small bath there would be some risk to other bathers, however.

Professional Secrecy and the Law

Q.—*As an M.O. at a mental hospital, am I legally entitled to tell the wife of a patient recently admitted the diagnosis of G.P.I., suggesting that she gets herself examined? Should I do this even if she is not under my medical care?*

A.—The test of the legality of an action is not whether it is specifically permitted by law but whether it is forbidden, or whether an action can be founded on it. In the present case there are two possibilities. (1) The doctor may be breaking a duty of secrecy; (2) he may be committing an actionable defamation. The duty of secrecy at law, apart from medical ethics, is not clearly laid down, and much doubt is felt whether it exists. Even if it does, it may surely be overridden by the need to protect the wife's health. Secondly, although to state of a man, either orally or in writing, that he is suffering from G.P.I. is doubtless defamatory, and gives a right of action, the action would fail if the doctor showed that his statement was true, or that it was made reasonably and in good faith to protect the wife's health.

Safe Milk for Children

Q.—*At what age would you allow a child to take unboiled milk? One may bring up a baby and infant on boiled or pasteurized milk, but obviously one cannot continue in modern society doing so indefinitely.*

A.—The short answer is that a child should have boiled milk until he is about 2 years of age and thereafter milk that has been efficiently pasteurized. It is surely easier to do this in "modern society" than in the last century—for example, since much more milk is now pasteurized. Moreover, legislation has been passed to make it compulsory, as soon as plant and personnel are available, for all milk to be pasteurized except from T.T. and "accredited" cows. When this becomes the practice all over the country the risks of liquid milk—not only for children—will be avoidable. Meanwhile, all milk for children should preferably be heat-treated. What the questioner is worried about probably is what happens when the child goes out to tea, or on holiday, or to a restaurant, or has milk at school. Procedure recommended in these situations is as follows: Tea parties, child take his own milk; holidays, especially if on a farm, milk to be boiled (a useful excuse is that it is too rich); at a restaurant—in London and large cities it will probably be pasteurized milk anyway, and if there is any doubt about it ask for it to be boiled or give the child something else; at school, inquire if the milk is pasteurized, and, if not, arrange for the child to have it boiled or as cocoa.

Acute Aspirin Poisoning

Q.—*Would you please state the symptoms of acute aspirin poisoning? Is there any evidence to prove it is a cumulative drug?*

A.—The symptoms of acute aspirin poisoning are those of salicylism. Deafness and headache occur first, and if the drug is continued or larger doses are given the patient suffers from vomiting, unconsciousness, delirium, dyspnoea, and deepened respiration. The pulse weakens and becomes irregular, epistaxis is common, and haemorrhage may occur from other parts of the body, such as haematuria and retinal haemorrhage. Idiosyncratic reactions may occur such as urticaria, erythema, or purpura. About 10% of asthmatics are aspirin-sensitive and develop violent paroxysms of asthma after taking the drug. A local gastric reaction may give rise to haematemesis. Aspirin is not cumulative in the ordinary sense—i.e., the drug itself does not accumulate in the body—but it may produce a cumulative effect by its action on the prothrombin of the plasma. Salicylic acid is related to the anticoagulant substance dicoumarol, and it is possible that continued dosage with aspirin might lower the prothrombin level to a haemorrhagic level.

Orchitis without Parotid Enlargement

Q.—*In a recent mumps epidemic in my unit (about 50 cases) I saw two cases of orchitis without any history of parotid enlargement, fever, sore throat, etc. Is this to be expected, or is it very unusual?*

A.—The mumps virus has particular affinity for certain tissues, which include the meninges, salivary glands, pancreas, testicle, and ovary. Normally the susceptibility of the salivary glands is much higher than testicular tissue; hence the virus tends to settle there first; but this is not invariably the sequence. Thus (*a*) orchitis preceding salivary gland involvement and (*b*) orchitis as the only manifestation of mumps have been encountered in the past. Both are uncommon. The factors which favour occasional resistance of all the salivary glands are unknown, but testicular susceptibility appears to bear a fairly close relation to sexual activity.

Prolactin

Q.—*Is there a lactogenic hormone which can be administered at parturition to stimulate the milk yield of the breasts in an otherwise normal woman of 35 years? Do the results justify the use of such a preparation?*

A.—There is a lactogenic hormone, usually called prolactin, secreted by the anterior lobe of the pituitary, and it is in large measure responsible for the initiation of lactation after parturition. It is available for clinical use and is administered by intramuscular injection. To stimulate lactation, treatment should be begun within a few hours after delivery rather than during labour, and a total of at least 1,000 i.u. should be given in divided doses during the first forty-eight to seventy-two hours—say, five injections of 200 i.u. each. The effect of such treatment is extremely variable and is, in any case, difficult to assess. There is good reason to question whether it is worth while, particularly as local reactions to the injections are not uncommon. However, the time is not ripe for a definite conclusion as to its merits, and meanwhile it is a treatment worthy of trial in special cases.

Nausea in Carcinoma of Stomach

Q.—*I am suffering from an advanced degree of cirrhous carcinoma of the stomach. My latest symptoms have been constant feeling of nausea with bouts of violent retching, with no result except frothy mucous. I have to take morphine occasionally, and this makes it worse. Can you suggest anything for my relief?*

A.—Morphine is rather apt to provoke vomiting, even in normal people. To prevent this it may be combined with atropine gr. 1/100, or dilaudid may be substituted, or opium by mouth. Wartime experiments on air-sickness and sea-sickness suggest that the two most effective remedies against nausea are barbiturates and hyoscine. Barbiturates usually have to be pushed to a sufficient degree to produce sleepiness, but hyoscine hydrobromide gr. 1/100 by mouth may relieve nausea and allow normal activity. It may be repeated two or three times daily. Lavage with a dilute solution of sodium bicarbonate, a teaspoonful to the pint, is the classical remedy for nausea and vomiting in carcinoma of the stomach; with practice it is not distressing and may be repeated two or three times daily. Injection of vitamin B_1 has been favourably mentioned, and older-fashioned remedies are tincture of nux vomica, 5 to 15 minims before meals, or a few drops of chloroform on a lump of sugar. Alvarez states that some women are able to relieve menstrual nausea by overbreathing till they become dizzy.

Sterilizing Paraldehyde

Q.—*In order to avoid any risk of injecting claustridia spores when giving intramuscular injections, how should paraldehyde be sterilized to avoid decomposition by oxidization?*

A.—The only method of ensuring the sterility of fluids which cannot be autoclaved is by filtration. Whether this is necessary is another question. We know of no evidence bearing on the possible bacterial contamination of paraldehyde, and of no record of an infection produced by injecting it; this, however, may only be because the practice is uncommon.

Haemoglobin and Plasma Protein Estimation

Q.—*Major-Gen. Ogilvie, in his article on May 5, speaks of bedside methods of estimating haemoglobin and plasma protein which have only been available within the last two years (paragraph on general health of the injured, p. 620). To what method does he refer?*

A.—The new methods referred to are those based on the determination of the specific gravity of whole blood and plasma by the copper sulphate method. This is based on the facts that plasma or whole blood dropped into a solution of copper sulphate of known gravity is encased in a sack of copper proteinate, and the gravity of this discrete drop is not changed for about 15 seconds. The rise or fall of the drop during this interval shows whether it is lighter or heavier than the solution. Copper sulphate solutions of known gravity are made with precision by diluting a stock solution, which is prepared either from weighed amounts of crystalline copper sulphate or from measured volumes of saturated copper sulphate solution. Standard copper sulphate solutions with gravities graded at 0.001 intervals suffice to measure the gravity of blood or plasma to ± 0.002. Three or four drops of blood or plasma and about a minute of time suffice for a determination. No temperature controls are needed. Line charts have been prepared for quick calculation of plasma proteins from plasma gravities, and of haemoglobin and haematocrit values from combined plasma and whole blood gravities. The haemoglobin values thus estimated appear, from comparison with precise oxygen capacity determinations, to be as accurate as haemoglobin values determinable by the better types of colorimetric procedures. The haematocrit values are less accurate, but are useful unless blood conditions are present which alter the specific gravity of the cells. If the blood cells are normal, cell counts also can be estimated from blood and plasma gravities. The technique is described in great detail in a paper from the Rockefeller Institute for Medical Research by R. A. Phillips, D. D. van Slyke, V. P. Dole, K. Emerson jun., P. B. Hamilton, and R. M. Archibald. Copies of the paper may be obtained from the Josiah Macy Jun. Foundation, 565, Park Avenue, New York 21, N.Y., U.S.A.

Care of Artificial Eye Socket

Q.—*What is the proper procedure for the day-to-day care of the socket in which an artificial eye is worn? Is it usual for there to be some redness and discharge in hot or smoky atmospheres? And, if not, what should be the treatment?*

A.—The amount of care required by an artificial eye depends upon the accuracy of the fitting. The better the fit the less trouble the eye will give. The eye should be taken out at night and the socket washed out with lotio acid. bor. night and morning. If there is a discharge, zinc sulphate gr. 1/4 should be added to the ounce of lotion. Any tendency of the lids to stick together in the morning should be combated by the application of clean vaseline to the roots of the lashes last thing at night. If the surface or edge of the eye should become rough, it should be repolished, or a new one obtained.

Local Sulphonamide Therapy

Q.—*What is the present view on local sulphonamide therapy? Is it contraindicated in all cases because of the danger of a patient developing hypersensitivity, or are some of the series worse, and/or some local conditions more prone to develop these? How would you desensitize a case?*

A.—Sensitization to sulphonamides has been observed chiefly after the powdering of wounds. Whether the amount used or nature of the lesion treated determines this effect is not clear. It seems probable that sensitization in these cases was made manifest only because so many of them were subsequently given sulphonamides by the mouth; after other forms of local use such treatment is much less likely to be given.

Whether the powder treatment of battle wounds has or has not been of value is one of the largest unanswered questions facing the medical historian of the war. The original evidence in favour of its use as a prophylactic in compound fractures in civilian practice appeared sound. For the more specific purposes of treating impetigo, a localized peritonitis, or an infected granulating area requiring a skin graft, local sulphonamide treatment is undoubtedly valuable. Penicillin will do most of these things even better, and is hence likely to supersede the sulphonamides in local treatment when supplies permit.

I know of no method of de-sensitization. (See also reply to a question published on Oct. 23, 1943, p. 533.)

INCOME TAX

Retirement from Partnership

"X. Y." ceased to be a member of a partnership as from March 1, 1945. He asks, "Am I liable to any income tax on the receipts for the last year?"

*** He is not liable to income tax on the source of income after March 1, 1945. The assessment for 1944–5 (presumably made on the basis of the earnings of the firm for 1943) covers the liability of all members of the partnership up to April 5, 1945. "X. Y." should therefore bear only tax on 11/12ths of his share of the 1944–5 assessment, and is not liable for any part of the tax to be assessed for 1945–6 on the basis of the earnings for 1945.

Purchase of Share of Book Debts

"BEE" bought a share in a partnership, paying £200 for a share of the book debts. Can he claim any deduction for this payment, seeing that he has to pay tax on his share of debts recovered by the firm?

*** No. The firm is presumably assessed on the basis of cash receipts, otherwise the point would not arise. The tax which "Bee" pays does not relate in fact to the debts he purchased; they may be included in calculating the profit for tax purposes, but the tax is paid for the year of assessment. If and when "Bee" sells his share of the partnership debts, he will not be liable to account for tax on the amount received—that will be a receipt of capital, just as the £200 is a payment of capital.

LETTERS, NOTES, ETC.

Health Education Lectures

Dr. ROBERT SUTHERLAND, medical adviser and secretary, Central Council for Health Education, Tavistock House, Tavistock Square, W.C.1, writes: I should be grateful if you would let your readers know that this council has now a balanced team of technical officers whose services are available to local authorities, educational institutions, and voluntary organizations for help in their health education work. This team consists of medical men and women with specialized experience in different health fields, two biologist-educationists, and an educational psychologist. Between them these officers are competent to cover most aspects of health and health education. Any of your readers who feel that they could make use of the services of these lecturers in any health education they may be carrying out can get further information from me.

Antiscorpion Serum

ALLEN AND HANBURYS LTD. write: In the *Journal* of April 28 (p. 618) Dr. Frank Marsh mentions that an antiscorpion serum was made before the war. We should like to point out that the Lister Institute makes a concentrated multivalent antiscorpion serum which we issue. This serum is obtained from horses that have been immunized against the venoms of the scorpions *Buthus quinquestriatus, Prionurus citrinus,* and *Buthus maurus.* The dose is the contents of one phial.

Clinical Photography

Dr. FRANK R. NEUBERT (London, S.W.15) writes: The medical profession has given surprisingly little attention to the art of clinical photography. Students are still entertained during lectures by lantern slides and epidiascope pictures which would, as often as not, disgrace the merest tyro in photography. Lecturers suffer them because they either illustrate, however badly, some rare condition about which they wish to speak, or are the only slides available. No general attempt is made to take advantage of modern photographic technique to produce pictures which would illustrate cases more clearly and add to the interest of the lesson. The same standard is accepted in illustrating textbooks, although modern works on dermatology provide exceptions, and some books on surgery owe much of their popularity to the quality of the illustrations. This state of affairs is due to the fact that, although most institutions have photographic apparatus of sorts, the men who use it are invariably laboratory assistants whose knowledge of and interest in photography are *nil*. Many doctors (whose work is shown regularly in salons and exhibitions) are expert photographers, and it is regrettable that more of their skill is not devoted to use of the clinical camera. Some diseases of which there are no good photographic records are gradually passing from our clinical ken. An opportunity exists for some firm or body interested in photography to compile a library of kinematic and static photographs, both in colour and in monochrome, from which writers and lecturers could obtain illustrations more worthy of modern medicine.

A Missing Infant

L. CLARE, divisional detective inspector, "D" Division, Metropolitan Police, Albany Street Police Station, N.W.1, asks us to state that about 4.30 p.m. on April 16 Maurice Stephen Jakubowicz, aged 8½ months, hair dark and sparse, eyes brown, well nourished, circumcised, vaccination mark on left arm, rash mark on both temple and back of head caused by eczema, top of left ear turned down was stolen from his perambulator outside Pemberthy's, 399, Oxford Street, W. Despite numerous inquiries this child is still missing, but on the same day its clothing was found near a static water tank a the back of Selfridge's. The tanks at the rear of Selfridge's hav been emptied without any further discovery. A photograph of the child appears outside every police station in the Metropolitan District, and all country forces have been given particulars and photograph. "It is thought that the child may be in need of medical attention, and therefore could you, in order to assist us, bring t the notice of your readers the fact that the child is still missing and how gladly we would receive any information. The father o the child is serving in the British Army, and is returning to th Continent shortly."

Disclaimer

Dr. W. EDWARDS (Ashtead) writes: May I disclaim responsibilit for the sensational article about myself which appeared in one o the Sunday papers on June 3? A reporter came during my morning surgery and produced the letter by me which appeared in las week's *B.M.J.* I understood he wished to quote it, and, as it ha been published, he plainly had every right to do so, whether objected or not. After leaving me he went on to the factory mentioned, where he obtained the story he actually wrote; but I knew nothing about this until it appeared in print.

Correction

We must apologize for a slip in the preparation of Dr. Pallot' letter for press (May 19, p. 714). His reference was to *Mrs.* Isab Wilde.

DIODOQUIN FOR CHRONIC AMOEBIC DYSENTERY IN SERVICE PERSONNEL INVALIDED FROM INDIA

BY

T. C. St. C. MORTON, O.B.E., M.D., F.R.C.P., D.T.M.&H., K.H.P.

A/Cdre., R.A.F.; R.A.F. Institute of Pathology and Tropical Medicine

The problem of treating resistant amoebic dysentery cases is arousing great interest both in the Services and in civil life, and it is felt that a report on the trial of an amoebicide, new so far as this country is concerned, is worth recording, although it is realized that sufficient time has not yet elapsed to be sure of the prospects of a complete cure in the present series of cases. Two of them had received no previous specific therapy, but all the others had had repeated maximum courses of emetine injections (12 gr.), with or without any further gut-sterilizing treatment such as emetine bismuth iodide (E.B.I.) by mouth combined with yatren retention enemata, and all these cases had experienced anything from 3 to 9 relapses before treatment with diodoquin. The majority had received carbarsone or stovarsol and numerous courses of sulphaguanidine or sulphapyridine. These cases had become resistant, and it was felt that the best prospect of cure was to try some other amoebicidal drug chemically as far removed from emetine, or one of the arsenicals, as possible. On discussing our problems the Director-General of Medical Services obtained for us a supply of diodoquin (5,7-diiodo-8-hydroxyquinoline), a product of the Searle Laboratories of the U.S.A., which had been introduced in that country since 1935 and appeared to be the most promising of the oxyquinoline compounds. It had been reported on very favourably by Craig (1937) and D'Antoni (1942).

Properties of Diodoquin

Diodoquin is a tasteless non-toxic compound containing 63.9% iodine, while chiniofon and vioform contain 28.9% and 41.5% iodine respectively. Diodoquin is extremely insoluble in water, dilute acids, or alkalis; because of its insolubility it does not produce the unpleasant purgation often experienced with the use of the other hydroxyquinoline compounds when given orally. The makers state that it is not absorbed, but David, Phatak, and Zener (1944) found that in some cases it gave rise to pruritus ani, which developed on the 4th to 5th day of administration and persisted for some days after the drug was stopped; no symptoms of iodism were observed, and increases in the blood iodine level were very irregular, varying from 45.6 micrograms to 437.25 mg. in man and experimental animals. Their conclusions were that the toxicity of an insoluble drug like diodoquin may depend on such factors as hyperacidity or intestinal stasis rather than on the actual amount of drug administered. In the present series of 78 cases two cases of intolerance were observed and two patients complained of mild pruritus ani; in no case were there any serious after-effects, and the patients were pleasantly surprised, after their previous experiences with emetine and E.B.I., at the non-toxicity and efficacy of the new treatment. Diodoquin is opaque to *x* rays, and radiographs show an even distribution throughout the large bowel. Lamblia are not affected by diodoquin, but Hummel (1940) states that *Balantidium coli* responds well to treatment with the drug.

Treatment

Three tablets of diodoquin, 3.2 gr. each, three times a day for 20 days, was the standard dosage adopted. In addition, in another series of cases the diodoquin was combined with yatren retention enemata for 10 days, and a small series showing either amoebic hepatitis or other evidence of deep infections received emetine injections as well. A small control series treated with the standard combined E.B.I. and yatren course is included for comparison; there was no selection of cases for this control course. All patients were sigmoidoscoped before and after treatment, and in 15 cases treatment was carried out on the typical sigmoidoscopic appearances alone, the stools being negative, although in all these 15 cases *Entamoeba histolytica* had been found previously.

Series I: Cases treated with diodoquin alone by mouth.—26 cases were treated with diodoquin alone—three tablets t.d.s. for 20 days. 17 cases were apparently cured, and follow-up examinations of 3 stools were negative two months after discharge from hospital. Two of these cases had received no previous treatment for dysentery. In addition, three cases with positive sigmoidoscopic findings but with negative stools were treated, and the lesions had healed at the end of the treatment. There were two relapses, and four cases were resistant to treatment. In one case active entamoebae were present at the end of the course. In another, ulcers were still unhealed at the end of one course. In a third, amoebic abscess of the liver developed three months later, although the stools were negative on readmission. One patient had an acute relapse, with active entamoebae. This was a very chronic case which had previously had nine relapses after E.B.I., yatren, etc. Another patient had petechial haemorrhages present in his rectum at the end of one course, although his stools were negative; these had disappeared after a second course. One case relapsed four months after treatment.

Series II: Cases treated with diodoquin for 20 days + yatren retention enema for the last 10 days of the course. This treatment was initiated as it was felt that lesions in the rectum might not be exposed long enough to diodoquin in the lumen of the bowel and that this was probably the cause of the relapse in the cases treated with diodoquin alone by mouth. Logically, one should have treated these cases with diodoquin retention enemata. This was done successfully in one case, but as supplies of the drug were restricted it was not possible to use this method in the other cases. 39 cases were treated. Enough time has not yet elapsed for a two-months follow-up in all cases, but the results to date are as follows: Cures, stools positive for *E. histolytica* before treatment, 22; cures, stools negative before treatment, but sigmoidoscopy typical, 8; resistant, 2; relapses, 7.

Series III: Emetine hydrochloride, 6 to 10 gr. by needle + diodoquin concurrently by mouth for 20 days; the last 10 days the patient received yatren retention enemata without a preliminary bowel wash-out.—This treatment was carried out in those cases showing symptoms of hepatitis, gross deep ulceration of the rectum, or a marked leucocytosis. 13 cases were treated, but follow-ups are not yet due in all of them. Results: Apparent cures, stools positive for *E. histolytica* before treatment, 9; apparent cures, stools negative before treatment, 2; relapse, 1; resistant, 1. In one case petechiae were present in the rectum; after one course this patient was given E.B.I. and yatren, and a further sigmoidoscopy showed a normal mucosa.

Series IV: Emetine bismuth iodide + a cleansing bowel wash-out with 2½% sod. bicarb. solution, followed by 250 c.cm. of a 2½% solution of yatren as a retention enema and 10 days' carbarsone, 4 gr. b.d.—Standard combined course: Emetine bismuth iodide, 3 gr. in cachets by mouth, together with a cleansing bowel wash-out of 2½% sodium bicarbonate, followed an hour later by 250 c.cm. of 2½% yatren, which is retained for 6 to 8 hours. This is carried out for 10 days and is then followed by carbarsone, 4 gr. b.d. for 10 days. In this series 24 cases were treated; 18 were cured, 6 relapsing. There were 3 primary cases, which were all cured. Two of the relapsed cases were cured with diodoquin. In 5 cases examination of the stools was negative, but sigmoidoscopy showed either ulcers or active pits. Two cases were most resistant to all forms of treatment. One has since apparently recovered with a high-protein diet and vitamin B_2+liver injections, and is back to full duty but under surveillance. The second is still under treatment. A roster of cases is being kept, and a follow-up of stools at two-monthly intervals after treatment is being carried out as a routine in all cases of dysentery however treated.

Results

Series I and IV have been observed and had 3 stools examined two months or longer after discharge from hospital. Series II and III have not all completed their period of surveillance since discharge from hospital.

Series	Apparent Cures	Resistant at End of Course	Relapses	Approximate Percentage of Failures After One Course
I	20	4	2	23
II	30	2	7	23
IV	18	1	5	25

Results of Series III are not included owing to the small number of cases.

Intolerance to Diodoquin

Two cases of intolerance to the drug were encountered.

Case 1.—A patient was being treated on his sigmoidoscopic appearances. Localized hyperaemia was present in his rectum, but stools and swabbings were negative. On the 14th day of treatment with diodoquin he had abdominal pain, diarrhoea, and blood and mucus in his stools, which were full of *E. histolytica*. He responded well to emetine and a second course of diodoquin and yatren enemata, with no further ill effects and apparent cure.

Case 2.—A severe case showing numerous ulcers with Dyak hair sloughs in his rectum and active *E. histolytica* in his stools. On the 14th day of the course he complained of abdominal pain, diarrhoea, and headache. The diodoquin was stopped, and the symptoms were rapidly relieved by emetine. A further course of diodoquin, E.B.I., and yatren was well tolerated, and sigmoidoscopy showed complete healing of the ulcers.

Records of Two Chronic Cases

The histories of two severe cases are given below; one was treated with diodoquin alone, the other received a course of emetine+diodoquin. These cases are worthy of record, as the first exemplifies how, by erratic and insufficient initial therapy, a case is rendered emetine-resistant, and how quickly it responds to treatment with diodoquin. The second is of interest because of the long-standing and atypical nature of the symptoms and the rapid response to specific treatment once the correct diagnosis was made.

Case 3.—Man aged 29. The first attack started in July, 1942, in India, the patient having been over-seas since Jan., 1942. Typical onset, with abdominal pain and bloody diarrhoea; 10+ stools a day. Treatment was as follows: First attack, 4 injections of emetine hydrochloride and 3 days' carbarsone. First relapse (24/7/42), salts only; second relapse (12/8/42), salts only; third relapse (19/9/42), salts only; fourth relapse (12/10/42), 12 injections of emetine hydrochloride; 6 days' carbarsone. Fifth relapse (12/1/43), 12 injections of emetine hydrochloride; 10 days' E.B.I. Sixth relapse (12/3/43), 12 injections of emetine; 14 days' retention enemata (? type); 14 days' N.A.B. retention enemata. From this relapse until landing in England on Jan. 5, 1944, he had several further relapses and was under almost continuous treatment. Nothing brought about any great improvement with the possible exception of the first few emetine injections in each course; for after complete 26-day courses active entamoebae were still found in the stools. On arrival in the United Kingdom he felt better, and stools were negative. In Feb., 1944, he had diarrhoea, with blood and mucus. Treated with emetine hydrochloride, yatren, and E.B.I. at a Service hospital, stools were negative after 7 weeks. In June he relapsed again and active entamoebae were present. He was transferred to another Service hospital. The liver was then found to be enlarged 2 in. below the right costal margin. White cells, 11,600, with a normal differential. Treated with emetine hydrochloride 1 gr. for 3 days; followed by E.B.I. 3 gr. for 7 days, together with 2% stovarsol retention enemata; followed by carbarsone 1 tablet b.d. for 10 days. Stools were then negative, but in view of continued liver enlargement it was decided to give 10 further injections of emetine hydrochloride, followed by 7 days' E.B.I. and stovarsol enemata. At the end of these two courses active entamoebae were still present, and sigmoidoscopy showed typical amoebic ulceration on the posterior wall at 12 cm. A full course of diodoquin was then started (3 tablets t.d.s. for 20 days). On Aug. 27 the course was concluded; 4 stools were negative for *E. histolytica* and macroscopically normal in every way. The liver was not palpable. White count normal. There were no ill effects from diodoquin therapy. Further follow-ups two months later were negative.

Case 4.—Man aged 43. From 1919 to 1921 he was in India in the Army, and had had a few attacks of diarrhoea, in one of which he noticed blood and mucus. He was treated with castor oil and some white powder. He returned to England, was demobilized, and worked first of all for 10 years as a salesman and then for 10 years as a bus conductor in London. On Oct. 15, 1941, he enlisted in the R.A.F. He suffered all this time from recurrent bouts of diarrhoea, during which he sometimes noticed blood and mucus in the stools, and for 15 years was treated by his own doctor. He states that the attack started with a "terrific pain" in the abdomen, vomiting, and then diarrhoea, which relieved the pain. He was given castor oil and bismuth and placed on a milk diet; the symptoms would then subside in two to three days and he would be free from further attacks for three months, during which period he would pass one formed stool a day. He had never had a stool examined or been sigmoidoscoped, but got into the habit of treating his attacks himself without calling in his doctor. He served in Canada in the R.A.F. from 1943 to Oct., 1944. On his return the attacks became more severe and he reported sick to his Station M.O., who examined his stools and found numerous active *E. histolytica;* he was admitted to hospital. On examination he appeared to be prematurely aged. His abdomen was generally tender to palpation, especially over the sigmoid, which was thickened, and his liver was palpable and tender 2 in. below the costal margin. On recta examination a fungating, soft, acutely tender mass could be felt some 4 in. from the anus; it was suggestive of an adenocarcinoma A proctoscope revealed an intensely hyperaemic mucosa with typical raised crateriform ulcers and a protruding ulcerated mass at 4 in suggestive of a neoplasm or amoeboma; numerous active entamoeba containing red blood corpuscles were easily obtained on gently scraping this mass. The patient was given six daily 1-gr. injection of emetine together with three tablets of diodoquin daily for 2 days; in addition, he was given 200 c.cm. of 2½% yatren as a reten tion enema from the 6th to 20th days without a preliminary bowe wash-out, and stovarsol 4 gr. b.d. from the 20th to 30th days. O sigmoidoscopy on the 30th day a linear healing ulcer was seen a the site of the amoeboma; this was painful to the touch, but th sigmoidoscope was passed to 25 cm. and revealed no evidence o further ulceration although the mucosa was lax and rugose. H was sent on 14 days' sick leave, and on his return sigmoidoscop showed that the ulcer was completely healed, but the mucosa wa granular and hyperaemic at the site of the ulcer, although his stool were completely negative. His liver was no longer palpable o tender, and he said he felt a new man. In view of the long-stand ing history it was considered advisable to give him a 10-day cours of E.B.I. and yatren. On examination three months later sig moidoscopy revealed a normal mucosa, and six consecutive stool were negative.

Conclusions

The claims as to the efficacy of diodoquin in amoebias advanced by the makers have not been fully substantiated s far as the treatment of chronic amoebiasis is concerned, a approximately one-third of the cases have relapsed. The dru however, is very useful in cases in which, owing to inadequat treatment consisting of repeated courses of emetine hydr chloride by the needle, the entamoebae appear to have becom temporarily emetine-fast. Here a course of diodoquin has o many occasions effected a dramatic cure clinically, and in 77 of a small series of cases this cure appears to have been perma nent. The administration of a new well-tolerated drug suc as diodoquin has a good moral effect on patients who have pr viously had repeated courses of a depressing drug such as E.B. especially when they notice rapid clinical improvement follov ing its use. There is reason to believe that in these resista cases a synergistic effect is produced by diodoquin that rende their entamoebae once more sensitive to emetine. The greate advantage of diodoquin is that it can be taken concurrent with emetine injections in cases of amoebic hepatitis, theret saving time, and I feel that this is its most useful role in t treatment of active amoebiasis over-seas. I would, howeve suggest a course of 6 injections of emetine hydrochlori ogether with 3 tablets of diodoquin t.d.s. for 20 days, in a ontrolled series of primary acute amoebiasis over-seas, to be ompared with a similar series treated with emetine, E.B.I., and atren. In chronic established infections a cure will eventually e effected by a blunderbuss therapy of courses of E.B.I. orally nd yatren enemata, followed by the 20-days standard course f diodoquin and ending with a 10-days course of stovarsol r carbarsone. The diet, a non-residue one, should be as ourishing as possible; it should contain a relatively high proortion of animal protein supplemented by vitamin preparaons containing the B_2 complex. A course of sulphasuxidine,) eliminate secondary bacterial invaders, should be given, and cently penicillin has been successfully used in severe cases r the same purpose, although neither penicillin nor sulphaxidine has any direct amoebicidal effect.

Summary

Diodoquin appears to be the best of the oxyquinoline group of ugs in the treatment of amoebiasis, and is a valuable addition the therapeutic remedies available for the treatment of this sidious and intractable disease. It is non-toxic in therapeutic ses, and is well tolerated in all but a small minority of cases.

The practice of treating amoebiasis with emetine alone cannot too strongly condemned; only a small percentage of cases are red, and the vast majority are rendered more resistant to further eatment with emetine and less amenable to treatment with any her available drugs.

I wish to thank the Director-General of the R.A.F. Medical Serces for his interest in these cases and for obtaining the supplies diodoquin. I am indebted to Fl. Lieut. Daly, R.A.F.V.R., who as the medical officer in charge of the wards, for his careful cording and helpful criticism; to Miss Sage, senior laboratory chnician, for her painstaking examination of countless specimens; d to Sgt. Greenfield, A.G., laboratory technician, for his technical sistance.

ESTORATION OF DIPHTHERIA IMMUNITY WITHOUT INJECTIONS

TOXOID PASTILLES BY MOUTH

BY

GUY BOUSFIELD, M.D., B.S.

ave long sought a means of immunization whereby injections uld be avoided entirely, but up to the present time I have t met with this degree of success. If, however, one could vise a method of *re-immunization* which could be applied to der children and adults without the production of functional sturbances of any kind a very considerable advance would ve been made.

So far as can be seen at present, the future of diphtheria munization will be concerned mainly with the treatment of ants aged 1 year, or slightly less. At this time of life the thod of administration is likely to continue to be the injecn. Considerable dosage of such antigens as A.P.T. can as rule be given without causing constitutional disturbance of y kind, at the same time bestowing an effective basal immuy. It is usually considered desirable, at the beginning of ool life, to boost this immunity by means of a further injecn of A.P.T., and this can generally be administered to young ojects without fear of producing sore arms or other ill effects. vertheless, there are fairly numerous persons of more mature —e.g., older school-children, hospital nurses, troops, etc. who, owing to various circumstances, may require remunization. Then one is confronted with the possibility sharp local or general reactions in some subjects, even when h a mild antigen as T.A.F. is employed, but more especially en injections of A.P.T. are given. Such results may occur en only Schick-positive reactors are inoculated, but when mmunizing injections are given to all and sundry, without vious Schick-testing to establish the need, the incidence and erity of local reactions and constitutional disturbance rise rply in adult age groups.

Jensen's (1937) method of instilling drops of formol-toxoid into the nostrils might have solved the problem if the procedure had not been rather impracticable, and if the danger of producing rhinitis could have been overcome (*Lancet*, 1941). It has not been thought worth while to pursue that form of treatment to any extent in this country.

In a limited number of subjects I demonstrated (Bousfield and King-Brown, 1938) that deep inhalation of the air of a room which was impregnated with finely atomized formol-toxoid was capable of producing an excellent rise in the antitoxin titre of the blood: this method I could not follow up, as experience showed that most of the volunteers became highly sensitized and developed allergic symptoms. I then attempted to pass formol-toxoid through the skin, in a neutral glycerin medium, with inconclusive results (Bousfield, 1944).

The present series of experiments is concerned with attempts to apply stimuli to the upper portion of the alimentary tract. The idea was suggested by the fact that, during an attack of diphtheria, absorption of some toxin from the mouth, fauces, and oesophagus might be a factor in the production of any subsequently acquired active immunity. If toxin *is* thus absorbed during the disease it seemed logical to investigate whether formol-toxoid, given in sufficiently large dosage, would be absorbed by *healthy* membranes in amounts which would provide an adequate stimulus.

I conceived the idea of a fairly firm gelatin sweet or pastille, containing about 100 Lf units of formol-toxoid, suitably sweetened and flavoured with some fairly neutral agent such as peppermint. I am variously indebted to Sir Alexander Fleming, Mr. L. B. Holt, of the Inoculation Dept., St. Mary's Hospital, and to Dr. Stanley White and the chief chemist of Messrs. Parke, Davis and Co., for the final production of the pastille, which I required, in the form of a gelatin disk. In preparing the disks the toxoid was added to the melted gelatin at a low temperature—about 40° C.—and the *p*H was adjusted to 6.5. The formol-toxoid which Mr. Holt supplied for the purpose was highly concentrated (2,000 Lf per c.cm.) and was of great purity: it was no less than 75% pure, in terms of protein, having been prepared by a method developed by Mr. Holt at St. Mary's Hospital.

Serum-antitoxin Tests on Adult Volunteers

As I personally am highly allergic to diphtheria antigens, I tried the effect on myself of sucking the toxoid disks—four each day, for seven days—and experienced no inconvenience of any kind. I then obtained five volunteers, bled them for preliminary antitoxin titration, and gave each of them 28 toxoid-gelatin disks to suck slowly, at intervals, four a day, for seven days. Fourteen days after the conclusion of treatment they were bled again, to see whether any rise in circulating antitoxin could be demonstrated as a result of the treatment.

Sir Percival Hartley kindly undertook all serum-antitoxin titrations for me; at his request neither the main purpose of the inquiry nor the details of the individual experiments were communicated to him, in order that the antitoxin determinations should be done "blind." The importance of this fact in considering results will not escape notice. The changes in the blood serum titres in my first five cases will be found in Table I.

Table I.—*Dosage, Four 100-Lf Disks Daily for 7 Days*

Case	Sex and Age (Years)	Previous Immunization or History of Diphtheria	Original Serum Titre (Units)	Titre 14 Days After Treatment (Units)
1	F 19	Diphtheria at 5 years; Schick-neg. at age 17	> 0·1 < 0·2	> 0·2 < 0·4
2	F 40	3 inj. diph. prophylactic 15 years ago. No post-Schick test	> 1·5 < 2·0	> 4·0, nearly 8
3	M 17	2 inj. 2 years ago, probably A.P.T. No post-Schick test	> 0·05 < 0·1	> 8·0 < 16·0
4	M 33	Had diphtheria at age of 6 years	> 0·02 < 0·05	> 1·5 < 2·0
5	F 45	Naturally Schick-negative 10 years ago	> 1·5 < 2·0	> 4·0, nearly 8

At this point it may be stated that none of the subjects who took the disks by mouth, in this or in subsequent experiments, experienced any inconvenience whatever, with the exception of one adult female who complained of persistent repetition of the flavouring element in the mouth. Constitutional symptoms were entirely lacking.

It will be noticed that all the subjects in Table I had previous experience of diphtheria antigens or of the disease, except Case 5, which was naturally immune and in which such experience can be assumed. All the cases showed a definite increase in antitoxin titre at the second examination, the change being very marked indeed in subjects 3 and 4, in which rises are of the order of 160 and 50 times respectively. These five subjects seem to demonstrate fairly conclusively that an effective boosting stimulus of toxoid had been passed across the mucous membranes, as I was unaware of any other form of extraneous stimulus to account for the increase of antitoxin. It seemed unlikely that five subjects, living in different homes, would all have chanced to come in contact with a stimulating dose of diphtheria infection.

The next step was to see whether a reduction of the number of toxoid disks would yield similar results. In this series only three of the disks were sucked daily by a further five volunteers. The results are shown in Table II.

TABLE II.—*Dosage, Three 100-Lf Disks Daily for 7 Days*

Case	Sex and Age (Years)	Previous Immunization or History of Diphtheria	Original Serum Titre (Units)	Titre 14 Days After Treatment (Units)
6	M 24	Blood antitoxin 1 year ago, 0·1 to 0·2 unit	> 0·1 < 0·2	> 8·0
7	M 18	3 inj. T.A.M., 1933; blood antitoxin, 1943, 0·01 to 0·02	> 0·01 < 0·02	> 0·05 < 0·1
8	F 19	3 inj. T.A.M. and Schick-neg., 1931	> 0·05 < 0·1	> 0·4 < 0·8
9	F 16	Blood antitoxin, 1943, 0·001; not immunized	< 0·001	< 0·001
10	F 18	Never Schick-tested or immunized	> 0·02 < 0·05	> 1·0 < 2·0

Four out of the five subjects gave a definite response to this reduced dosage, Nos. 6, 8, and 10 showing most marked improvement in antitoxin titre. Case 9 is of interest. This subject had apparently never had an effective primary stimulus in her life, and proved, furthermore, to be relatively difficult to immunize. When she failed to respond in the above experiment, I attempted to immunize her by means of three well-spaced injections of 1 c.cm. of T.A.F. A Schick test performed three months later was still definitely positive, and she required a fourth injection of T.A.F. to render her Schick-negative.

I then inquired whether the dosage of toxoid could be reduced still further. The original highly concentrated and purified toxoid, which Mr. Holt had supplied, had become exhausted. It was clearly not practicable to utilize such a refined product on a large scale on account of expense, and a relatively crude formol-toxoid, of about 50 Lf per c.cm. potency, was used for the preparation of the next supply of disks. Messrs. Parke Davis overcame the difficulty of including the larger volume of antigen in a disk of similar size to those supplied formerly. On account of the use of this relatively impure formol-toxoid, I again controlled the possibility of allergic trouble by sucking a number of the disks personally before handing them to others, without ill effect. Table III shows the effect of administering only two of these new disks (each containing approximately 100 Lf units) daily, for seven days, to a further group of five subjects.

TABLE III.—*Dosage, Two 100-Lf Disks Daily for 7 Days*

Case	Sex and Age (Years)	Previous Immunization or History of Diphtheria	Original Serum Titre (Units)	Titre 14 Days After Treatment (Units)
11	F 15	Immunized 2 years ago	> 0·1 < 0·2	> 0·2 < 0·4
12	F 14	Immunized early in life	> 0·05 < 0·1	> 0·05 < 0·1
13	F 16	Immunized at age of 4; re-immunized at 11 years	> 0·005 < 0·01	> 0·01 < 0·05
14	F 18	Immunized 5 years ago	> 0·01 < 0·02	> 0·05 < 0·1
15	F 19	Immunized at age of 11	> 0·01 < 0·02	> 0·05 < 0·1

It will be noted that the reduced dosage produced definite rises in the antitoxin titre in four cases out of five, though the improvement is not as great as was obtained by the use of three or four disks daily. No change was found in the titre of Case 12. This may indicate that the stimulus was insufficient or that the subject was unusually resistant to a stimulus the size of which would ordinarily be found to be moderately satisfactory. On the whole I am of the opinion that three 100-Lf disks daily for one week is the smallest dosage which should be applied to adults if a marked increase in the antitoxin concentration of the blood is sought.

It was now desirable to determine if the stimulation took place only between the lips and the lower end of the oesophagus or whether, in any circumstances, absorption of any undestroye toxoid took place through the gastro-intestinal membranes. expected that rapid destruction would occur in the stomach My first attempt was a failure. I dipped a large number o the disks into melted gelatin to coat them, the dipping being s rapid that I did not expect to harm the toxoid. One group o volunteers swallowed some of these coated disks rapidly wit water, thrice daily, while others sucked them slowly in the sam dosage, the total taken being 21 disks in each case. Clearly had damaged the toxoid in the dipping process, as neither thos who swallowed nor those who sucked showed any change at al in their antitoxin titrations, and I wasted a number of ver valuable volunteers.

The problem was then approached from a different angle Instead of dipping the disks in gelatin after manufacture som toxoid was put up in capsules in a gelatin mass. These coul be swallowed at once with a draught of water. Four subject undertook to do this, and the experiment was controlled b giving the same toxoid dosage in plain disk form, to be sucke slowly by another group. The results are given in Table IV.

TABLE IV.—*The Effect of (a) Swallowing 100 Lf. of Toxoid i Gelatin Mass, Thrice Daily for 7 Days; and (b) the Effect of Sucking Three 100-Lf Disks Daily for the Same Period*

(a) Effect of Swallowing Toxoid

Case	Sex and Age (Years)	Previous Immunization or History of Diphtheria	Original Serum Titre (Units)	Titre 14 Day After Treatme (Units)
26	F 19	Immunized 4 years ago	> 0·4 < 0·8	> 0·4 < 0·8
27	F 20	Nat. Schick-neg. 18 months ago	> 1·0 < 2·0	> 1·0 < 2·0
28	F 17	No history of either	> 0·1 < 0·2	> 0·1 < 0·2
29	F 32	Nat. Schick-neg. 6 months ago; reported to have had diphtheria twice	> 0·4 < 0·8	> 0·4 < 0·8

(b) Effect of Sucking Toxoid

Case	Sex and Age (Years)	Previous Immunization or History of Diphtheria	Original Serum Titre (Units)	Titre 14 Day After Treatme (Units)
30	F 37	Diphtheria as a baby	> 0·1 < 0·2	> 1·0 < 2·0
31	F 30	No history of either	> 0·1 < 0·2	> 0·4 < 0·8
32	F 19	Immunized 4 years ago	> 0·005 < 0·01	> 0·1 < 0·2
33	F 55	Diphtheria at 10 years	> 0·2 < 0·4	> 2·0 < 4·0
34	F 39	Nat. Schick-neg., 2 years ago	> 0·2 < 0·4	> 0·4 < 0·8
35	F 33	Positive diph. swab during attack of scarlet fever 10 years ago	> 0·05 < 0·1	> 1·0 < 2·0
36	M 24	Nat. Schick-neg. 2 years ago	> 0·4 < 0·8	> 0·4 < 0·8

From the above it will be seen that none of the subjects wh swallowed the toxoid showed any antitoxin rises, whereas all thos who sucked the disks showed an increase, with the exception Case 36. It is interesting that he sucked the residue of an ear supply of disks, all the other control cases having been given a ne batch. Case 36 may thus have been one of those individuals wh respond to stimuli only with difficulty, or the disks he sucked ma have lost Lf value.

Consideration of the results in the above table suggests mo strongly that the stimuli responsible for increases of titre tak place only between the lips and, at the lowest, the lower en of the oesophagus. The method will probably be limited use to such subjects as are old enough or intelligent enough suck the disks slowly.

I also desired to find out whether, in the case of persons wh had only negligible quantities of antitoxin in their bloods, th titre could be raised by repetition of the toxoid-sucking pr cedure at intervals. In my abortive gelatin-coated dis swallowing and sucking experiment I had come across thr volunteers who had less than 0.001 of a unit of antitoxin p c.cm. in their bloods. This suggested that they might nev have possessed any basal immunity, in spite of the fact th they were of mature adult age. Some weeks after the fi experiment I gave them a further 21 disks—one to be suck thrice daily—waited a fortnight after completion of the trea ment, and then repeated the 21-disks course. After a furth 14-day interval a third course of disks was given, and a fo night later the subjects were again bled. Sir Percival Hartl once more reported less than 0.001 unit of antitoxin in all thr cases. It thus seems probable that the method, at any rate its present form, does not provide a sufficiently powerf stimulus for the purpose of primary immunization. A higher concentration of toxoid in the disks, or a method of prolonging the stimulus, such as some form of chewing-gum, might still be made to operate as a primary stimulus. Further work on such lines is indicated.

Investigations on Children, using a Modified Schick Test

The next stage was to see if the treatment could be applied to children who, having been satisfactorily rendered Schick-negative by means of prophylactic injections some years before, had been found to have relapsed to the Schick-positive state. Circumstances did not permit of bleeding these children, so I had to work by the Schick standard. It was first necessary to determine the effect of the stimulus provided by the amount of toxin present in the test dose of 0.2 c.cm. of Schick toxin. I Schick-tested a large number of children immunized some years before and found that 21 cases had relapsed to Schick-positive. Without giving any further injections I retested these 21 children three weeks from the date of finding them Schick-positive. To my surprise no fewer than 16 of the 21 had become Schick-negative as a result of the stimulus provided by the former test. It was thus clear that a routine Schick test for the purpose of finding positive cases on which to test the toxoid disk was a complicating factor, making it difficult to select groups suitable for comparative tests. Accordingly I resolved to find out whether testing with a half-dose of Schick toxin produced a lower conversion rate. Twenty-six children who had relapsed to Schick-positive were thus identified from another large group of subjects who had been previously immunized by myself. When I tested these twenty-six children again three weeks later I found that 13 had become Schick-negative as a result of the stimulus provided by the previous test in the reduced dosage of 0.1 c.cm. This result was disappointing; but I could not take bloods, so I was forced to work on the half-Schick dose for sorting-out purposes if I wished to try the effect of the disks on children.

Using the half-dose Schick test, I identified a further group of children who had relapsed to Schick-positive; I gave 17 of them three toxoid disks daily for a week, and retested them 14 days after completion of the treatment. All proved to be Schick-negative then. Three other relapsed children were given only two disks per day for a week, and 14 days after conclusion of treatment two had become Schick-negative, while one remained positive.

Thus, so far as it is possible to infer anything from Schick-test-controlled work, the observations on the volunteers who were bled are supported by these experiments in the children. This was only to be expected, but it was necessary to find out whether children of from 4 to 14 years of age could, on the whole, be relied upon to suck the disks slowly enough. There seems to be good reason to believe that they can be trusted to do so. Experience might enable one to produce the disks as a really attractive sweet, and this would ensure that the parent would not be allowed to forget to administer the treatment.

I attempted to amplify the evidence by investigating children resident in an institution who had a history of some previous immunization or of having been Schick-negative in the past. In my sorting-out process to find relapsed cases the few Schick-positive readings which I obtained were mostly so pronounced that I felt doubtful about their alleged original natural Schick-negative state. In many years of practical experience I have not found that natural Schick-negative reactors relapse to the intense degree of positive reaction observed in these cases, though most of the subjects were supposed to have been naturally immune formerly. Administration of disks to the children was largely a failure, and, on the evidence which I have offered above in the blood–antitoxin tables, I am of the opinion that these children had probably never reached the Schick-negative level in the past. This may serve to confirm the opinion which I have stated above—that the disk treatment is insufficient as a primary stimulus, and will prove adequate only when the subject has, at some time previously, reached the degree of training in antitoxin production which is revealed by a negative Schick test. All relapsed cases *which were previously immunized by myself,* and which had three disks daily for seven days, proved to be Schick-negative 14 days later, as compared with the control group, in which one-half of 26 cases became Schick-negative as a result of the 0.1 c.cm. Schick-toxin stimulus when tested again at the same interval as the children who sucked the disks.

Effect of Disk Treatment on Subjects having only Small Quantities of Circulating Antitoxin

There will be those who will be especially interested in this aspect of the question, and, to save a further summarizing table, I would draw attention to the following cases: Cases 7 and 9 (Table II), Cases 13, 14, and 15 (Table III), and Case 32 (Table IV). I repeat that I was unable to obtain a response from any of my four cases which had less than 0.001 of serum-antitoxin.

The above work demonstrates, I believe for the first time, that antitoxin-producing stimuli can be passed effectively across the mucous membranes of the upper portion of a healthy alimentary tract. Much work remains to be done to verify my results and to determine whether the method is applicable in the case of other antigens, such as tetanus toxoid, haemolytic streptococcus toxin, and the like. I feel that the findings should be made known at this stage so that others, who may have greater opportunities, may pursue the matter.

Summary

A method of providing a stimulus to the upper part of the alimentary tract by means of toxoid-impregnated gelatin disks is described.

The method seems to be generally effective in subjects who have any demonstrable amount of antitoxin present in the blood, or who are definitely known to have reached the Schick-negative level at some time in the past.

Rises in serum-antitoxin content are very striking in some of the cases.

While I find no evidence that the method will suffice to provide an adequate stimulus for primary immunization, it appears to be generally applicable to children and adults who have ever been immune in the past, provided that the age and intelligence of the subject are sufficient to ensure that the disks are sucked slowly. Modification of technique might still render primary immunization feasible.

The treatment can be administered to immune and non-immune subjects impartially without fear of producing local or general reactions, and thus, in cases which are *known* to have been immune in the past, a Schick test is not essential before using this method of re-immunization.

In view of the findings in the case of diphtheria formol-toxoid there seems to be an indication for pursuing the investigations in the case of other antigens, such as tetanus toxoid, where a rise in antitoxin titre is sought in order to boost a previously bestowed immunity.

While attractive to needle-shy children, the greatest value of such a method might be in dealing with adults—e.g., nurses or men in the Services—when it is so important that constitutional disturbance shall be avoided.

More research will be necessary in the matter of stabilizing the disks, so that they could safely be given a *long* period of legitimate use before expiry date. It would also be necessary to eliminate more of the formalin in order to produce the disks in the form of a sweet which would be really attractive to children.

In addition to the help I have already gratefully acknowledged, I wish to thank Sir Alan Daley, Dr. Anderson (M.O.H., Heston and Isleworth), Dr. O. W. Roberts (medical superintendent, Dulwich Hospital), and Drs. Smith and Taylor, of the London County Council medical staff, for the kind provision of facilities. I am also greatly indebted to the nurses, health visitors, public health department staff, and sanitary inspectors who volunteered for the blood investigation experiments.

According to reports in the Swedish press, Prof. Ragnar Granit, of the Neurophysiological Institution at the Carolinian Institute in Stockholm, has received a donation of 200,000 kronor (£11,765) from the Rockefeller Foundation. The grant is to be distributed over a period of five years. Recently it was decided to incorporate Prof. Granit's institution in the Nobel Institute of Medicine and to erect a special building for the institution in the neighbourhood of the Carolinian Hospital on the northern outskirts of Stockholm.

OBSERVATIONS ON SO-CALLED THYROTROPIC EXOPHTHALMOS

BY

Prof. HERMANN ZONDEK, M.D.

AND

ALBERT TICHO, M.D.

(From the Biccur Cholim Hospital and Dr. Ticho's Ophthalmic Hospital, Jerusalem)

Exophthalmos is known to be one of the main features of Graves's disease. It was first described by Parry in 1815. Exophthalmos may vary greatly in degree and take very different courses. Whereas in most cases it is stationary and does not endanger the eyeball, in some cases the extreme protrusion of the globe may lead to oedema of the lids, injection of the conjunctivae, chemosis, lagophthalmic keratitis, ulceration of the corneae, and finally even to loss of the eye. These two entirely distinct forms of exophthalmos are therefore basically different, and the latter, owing to its progressive character, is termed "malign" exophthalmos.

Until a few years ago exophthalmos was assumed to occur with Graves's disease only, and thus to be of purely hyperthyroid origin. Of late, however, clinical and experimental investigations have clearly shown that, besides the thyrotoxic form, there must be another—to be attributed to the pituitary body: in particular, the thyrotropic factor of the anterior pituitary lobe was held responsible for its occurrence (thyrotropic exophthalmos).

Loeb and Friedman in 1932 produced exophthalmos in guinea-pigs by injecting an acid extract of anterior pituitary of cattle. This exophthalmos, however, always regressed when the injections were discontinued, and the same occurred under narcosis and after death. Experimentally produced exophthalmos must therefore differ fundamentally from that occurring in man. Marine and Rosen in 1934, and Smelser in 1936, produced exophthalmos in guinea-pigs by injecting thyrotropic hormone of the anterior pituitary lobe; such results were even more readily obtained when thyroidectomy had been performed prior to the injections. Friedgood in 1934 also found that exophthalmos due to the thyrotropic hormone deteriorated on reduction of thyroid function, particularly so when the basal metabolic rate fell.

As to the thyrotoxic form of exophthalmos, two factors must be considered most important from the aetiological point of view. The first is the contraction of Mueller's palpebral muscles owing to increased sympathetic stimulation. These muscles exert a pull on the upper and lower poles of the globe through connexion with expansions from tendons of the upper and lower rectus muscles to lid tissues. Contractions of these muscles tend to produce lid retraction and proptosis. Landstroem's circular muscle, too, exerts a direct concentric pull on the globe. It should be noted, however, that even now evidence that increased sympathetic tonus is responsible for the ophthalmic manifestations in human Graves's disease has not been uniformly established, since sympathectomy has proved entirely ineffective in the treatment of exophthalmos in man. The second factor is the adynamia of the recti which normally retract the eye globe. It is noteworthy that it is not merely of late that adynamia of the recti has been assigned a part in the development of exophthalmos; for Cooper (1849), later Moebius (1886) and Lemke (1894), and more recently Sainton and Hesse in 1931, and Plummer and Wilder (1935), have expressed the same opinion. One of us (H. Zondek) was able to show in 1938 that in one case adynamia of the eye muscles led to a condition resembling complete ophthalmoplegia which could be temporarily relieved by the use of prostigmin. The great significance of the adynamia and muscular metabolism in Graves's disease induced one of us (H. Zondek), in 1935, to classify a certain form of this disease as its "muscular type" (*Diseases of the Endocrine Glands,* 1935, p. 157; 1944, p. 162). A third factor is the occurrence of anatomical changes. Within the orbit they are generally not very marked, and in particular the extrabulbar muscles usually are of normal shape and consistence. In some cases, though, general wasting of muscle fibres, accompanied by loss of striation, fibrillation, and amorphous granulation of sarcoplasm, is found. (Burch, 1929; Naffziger, 1933). For details see the exhaustive paper by Mulvany (1944).

With regard to thyrotropic exophthalmos, the phenomenon of proptosis seems to play a far more important part in its development than the widening of the palpebral fissures. There is neither lid spasm nor raised sympathetic tonus. The globe cannot be pushed back into the orbit, and owing to increased retrobulbar pressure such attempts are very painful. With thyrotoxic exophthalmos this is not so. The strong pressure acting on the eyelids from behind results in lid congestion, oedema, and chemosis, which are probably due to compression of the palpebral venous arcades. The lids press on the corneae, and this and the lagophthalmos lead to ulcerations and necrosis in extreme cases. The most important cause of the proptosis must be sought in muscle disorders such as (1) diffuse extense fibrosis, (2) oedema, (3) abundant round-cell infiltration, and (4) a special type of degeneration resulting in fibrosis or disintegration and absorption of muscular fibres (Mulvany). From the subjective point of view it is typical that patients suffering from so-called thyrotropic exophthalmos complain of pains, epiphora, photophobia, diplopia, and difficulty in convergence, whereas patients with thyrotoxic exophthalmos are usually free from such troubles. So-called thyrotropic exophthalmos—which, by the way, mainly occurs in male patients—generally seems to assume far higher degrees of proptosis than the thyrotoxic; the so-called malign exophthalmos (see above) mostly corresponds to the thyrotropic. It remains to be seen, however, whether milder degrees of exophthalmos, and in particular those without any accompanying signs of hyperthyroidism, will also fall into this group.*

Which clinical facts lead us to the conclusion that exophthalmos is not in all circumstances of hyperthyroid origin? (1) It must be remembered that some cases of exophthalmos not only are not improved but are even considerably harmed by thyroidectomy (see Case III). (2) The thyrotropic hormone in the serum is abnormally high with so-called thyrotropic exophthalmos, whereas the opposite is true of the thyrotoxic form. (3) Thyrotoxicosis accompanying so-called thyrotropic exophthalmos is usually comparatively mild and in striking contrast to the degree of ophthalmic manifestations. (4) Exophthalmos may also occur with hypothyroidism. (5) We think that the association of exophthalmos with Hand-Schueller-Christian's disease may possibly shed some light on this problem. Many authors maintain that exophthalmos in these cases is due to mechanical processes only. This assumption, however, is not generally agreed upon. If this mechanical theory be not true of all cases the coincidence with diabetes insipidus that is more or less characteristic of this disease would, rather indicate involvement of the pituitary gland or the diencephalic nuclei, since the thyroid gland does not have any part in it.

We have examined three cases of excessive exophthalmos (one post-operative) which, according to the above differentiation, ought to be classified as the so-called thyrotropic type of the disease. How very rare such cases are is demonstrated by the fact that one of us (A. T.) found among 150,000 ophthalmic patients only these three cases.

Case I

A man 47 years old. Family and previous history negative. The patient had always been healthy until about seven years ago, when he contracted influenza. Thereafter he noticed for the first time some swelling of the eyelids and slight protrusion of the eyeballs. This condition remained stationary until about six weeks ago, when the globes grew more and more prominent. Three weeks ago he developed nervousness and profuse perspiration. He had lost 3 kg. during the past three years.

Examination revealed extreme exophathalmos, especially of the left eye (see below); no goitre; pulse rate, 104–110; blood pressure, 130/75 mm. Hg; no adynamia; no tremor; reflexes normal; visceral organs, nothing abnormal. Urinalysis: urobilinogen increased, otherwise nothing abnormal. Blood count: R.B.C., 4,000,000; Hb, 85%; W.B.C., 7,000; differential count, normal. Glucose-tolerance test: 103, 154, 147, 181, 176, 163 mg. per 100 c.cm. Limbus capillaries normal. Heart radiologically normal. Radiograph of the skull:

---

* Just before this paper went to press we had the opportunity of observing a fourth case, which, although showing typical features of pituitary-diencephalic disorder such as high blood cholesterol level, deformation of the sella turcica, and changes in the osseous skull, lacked all signs of malignancy.

sella turcica enlarged; osseous outlines of the sella badly defined; frontal region of the skull considerably deficient in lime. B.M.R. + 60%. Eyes:—Chemosis and corneal ulcerations of the left eye. The degree of proptosis could not be measured on the left, the Hertel ophthalmometer going only as far as 30 mm., but was estimated to be about 35 mm. On the right it amounted to 30 mm.

The patient was given di-iodo-tyrosine (200 mg. a day for 10 days —i.e., a total of 2,000 mg.). When seen again after having finished this course the exophthalmos had become less (L. 30, R. 27 mm.). The limbus capillaries were of normal width and formation. When seen once more after the lapse of another week without any specific treatment, the pulse rate had dropped to 84 and the blood pressure to 115/80 mm. Hg. Exophthalmos—L. 28, R. 26 mm. No chemosis. Good lid closure. The corneal ulcerations were turning into scars. Surgical closure of the palpebral fissure, which had been attempted before the patient came under our observation but had not yielded any results, was now carried out without any difficulty.

Case II

A man aged 57. Family and previous history negative. The patient's left eye had been bad for two years, the right for one year. Otherwise he was all right until eight months ago, when he started complaining of loss of weight, heart palpitations, and nervousness. The basal metabolic rate was said to have been +40% six months ago. For the past three months the patient had been taking 15 drops of Lugol's solution a day.

Condition on examination:—Pronounced exophthalmos (see below); no goitre; pulse rate, 96; blood pressure, 155/70 mm. Hg; tremor of fingers and tongue; slight adynamia; visceral organs, nothing abnormal; reflexes normal. Urinalysis, nothing abnormal. Blood count: R.B.C., 4,600,000; Hb, 105%; W.B.C., 7,000; differential count, normal; blood calcium, 11.4 mg. per 100 c.cm.; phosphorus, 5 mg. per 100 c.cm.; cholesterol (two different readings), 294 and 375 mg. per 100 c.cm. Glucose-tolerance test: 88, 177, 170, 48, 183, 141 mg. per 100 c.cm. Limbus capillaries partly narrow, otherwise without abnormal findings. B.M.R. +19%. Fluoroscopic examination of the heart showed nothing abnormal. Radiograph of the skull: Sella turcica uniformly enlarged; very thin skull bones, especially the base, which was extremely thin and atrophic; vascular congestion, as made evident by widening of the meningeal vessels. Exophthalmos—R. 27, L. more than 30 mm.; congestion of ciliary vessels, insufficient closure of the eyelids; left optic disk pale but well defined.

The patient was given prominal and di-iodo-tyrosine (a total of 2,000 mg.) for 10 days. At the conclusion of this course his exophthalmos was found to have decreased by 1 to 2 mm. He was again given di-iodo-tyrosine, for five days (i.e., 1,000 mg.). After the lapse of another five days he felt much better; pulse rate, 4-90; blood pressure, 130/50 mm. Hg. The left eye could be closed better (on extreme closure there was about 3 mm. of uncovered globe left) and was less inflamed. He was then given 500 mg. of di-iodo-tyrosine a day for five days (i.e., a total of 2,500 mg.). When he was seen again he had lost almost all his general complaints; pulse rate, 76. The left eye could be closed almost completely (about 1 mm. uncovered globe left). Blood cholesterol, 90 mg. per 100 c.cm. Di-iodo-tyrosine was continued in reduced amounts (200 mg. a day for a week). Exophthalmos—R. 27, L. 29 mm. Thereafter the patient was submitted to *x*-ray irradiation of the pituitary gland. During this treatment the left eye seemed more inflamed and its closure less complete. Unfortunately the patient left Jerusalem directly after the course of irradiation was completed, so that its results could not be adjudged. He wrote after a few months, when he seemed to be rather satisfied with his general condition as well as with the state of his eyes; but he did not give any particulars, and had apparently not been seen by any doctors.

Case III

A man 46 years old. Family and past history irrelevant. For the past two months there had been diarrhoea, loss in weight, profuse perspiration, heart palpitations, trembling of the fingers, and progressive exophthalmos. The B.M.R. was + 25% in the beginning and + 15% after complete rest some weeks later. While resting the patient had gained in weight, but the remainder of the above symptoms were unchanged. The state of the patient's eyes had even taken a turn for the worse: the globes had steadily protruded, and consequently both eyes had got inflamed, lid closure had become insufficient, and the vision decreased.

Condition on examination:—Exophthalmos (see below); no goitre; pulse rate, 100; blood pressure, 145/65 to 175/90 mm. Hg; tremor of tongue and fingers; no adynamia. Visceral organs, N.A.D. Reflexes normal. Urinalysis, nothing abnormal. Blood count: R.B.C., 080,000; Hb, 80%; W.B.C., 5,800; differential count, normal; ood cholesterol, 182 mg. per 100 c.cm.; B.M.R. + 40%. Eyes: ellwag's sign positive; Moebius's and Graefe's signs negative. Exophthalmos—R. 24, L. 21 mm. (two months previously the spective measures had been R. 19, L. 16 mm.). Radiographs of e sella turcica were without pathological findings.

When we saw the patient again about five months later he had undergone thyroidectomy some four months before. He said that only one day after operation his sight had been clear, whereas afterwards he developed keratitis, conjunctivitis, and pronounced lacrimation. The eyes had protruded at a great rate (R. from 24 to 29-30 mm., L. from 21 to 24 mm., within four weeks). Graefe's, Moebius's, and Stellwag's signs positive. Lid closure accordingly became still more insufficient (R. 12, L. 3 mm.). The thyrotoxic symptoms had subsided, though gradually. The basal metabolic rate, which had dropped to + 15% after operation, had risen again to + 38% at a reading taken two weeks ago. (The patient admitted, however, that he had been very nervous at the time.) Exophthalmos was extreme (see above); pulse rate, 70; blood pressure, 135/80 mm. Hg; no tremor; no adynamia; normal reflexes; visceral organs, nothing abnormal; limbus capillaries on microscopical examination, normal. Radiograph of skull, nothing abnormal; B.M.R., + 29.5%.

The patient was given prominal and di-iodo-tyrosine (2,000 mg. within 10 days). When coming back after the lapse of three weeks he stated that for the first two weeks he had felt much better, lid closure having become easier and eye movements less inhibited. He had gained 3 kg. in weight, and made no complaint as to his general condition. Exophthalmos—R. 26, L. 22-23 mm.; B.M.R. +10%. Di-iodo-tyrosine was given again (100 mg. on alternate days for one month). When seen after the end of this course the patient was complaining of some nervousness. His eyes were not controlled on this occasion, but the exophthalmos appeared stationary, or even somewhat improved, and the signs of irritation were less pronounced than before. He was given quinine and prominal, and some time later *x*-ray irradiation of the pituitary gland. During irradiation the exophthalmos was: R. 25, L. 20 mm. General condition as above. The patient was given another course of di-iodo-tyrosine (a total of 2,000 mg. within 10 days). Thereafter he was able to close the left eye completely, whereas the right remained 4 mm. open on extreme closure. He was given quinine and di-iodo-tyrosine alternately (the latter amounting to another 2,000 mg.). One month later the patient stated that he was working hard and felt quite able to do so. Exophthalmos—R. 24-25, L. 20-21 mm. (See Figs.)

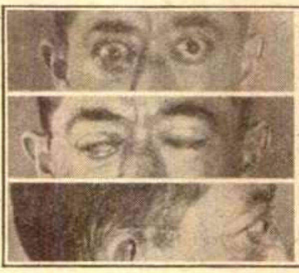

FIG. 1.
Case III before treatment

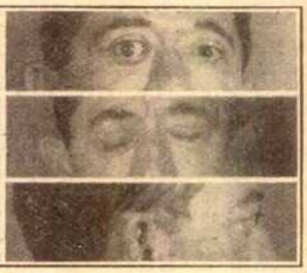

FIG. 2.
Case III after treatment

Di-iodo-tyrosine and quinine were given at regular intervals, and three months later another irradiation to the pituitary gland was started as the exophthalmos had remained stationary for the last few months. No visible results were seen after irradiation, so that two months later another course of di-iodo-tyrosine was given. When seen again the exophthalmos had scarcely changed (R. 23.5, L. 22 mm.), but the eye movements were free and easy. Lid closure was nearly complete. Blood cholesterol, 228 mg. per 100 c.cm. After one injection of a mercurial diuretic the patient felt much better subjectively, although the objective state had not greatly changed.

Discussion

The two cases of extreme exophthalmos accompanied by comparatively mild hyperthyroidism show more or less extensive changes in the osseous skull (bone atrophy round and above the sella turcica and moderate enlargement of it in Case I, extensive decalcification of the whole skull, and some uniform enlargement of the sella in Case II). Both cases had diabetic glucose-tolerance curves. These findings point to diencephalic or pituitary-diencephalic disorders. In Case II the blood cholesterol was found to be unusually high (in Case I, unfortunately, it was not examined), which suggests that this case cannot be designated as pure hyperthyroidism.* We should like to add that we often found such abnormally high blood cholesterol values in processes localized to the pituitary-diencephalic region. This matter will be reported upon on another occasion. Neither the above metabolic nor the osseous changes were met with in Case III (post-operative exacerbation of the exophthalmos).

---

* Another patient who came under our observation just before this paper went to press also had an abnormally high blood cholesterol level.

With regard to the pathogenic part played by the thyrotropic factor in this connexion, the following facts ought to be taken into consideration; the results of the animal experiments as described above seem conclusive. (The most suitable animals for these experiments are guinea-pigs, less so rabbits and rats.) In our opinion, however, it is very doubtful whether the results of experimental work may be applied to human pathology without any reservation. According to knowledge acquired thus far, no influence whatsoever of the thyrotropic factor on volume and water content of the extra-orbital muscles has been established. Another argument against the pathogenic part played by the thyrotropic hormone is the fact that exophthalmos is very rarely encountered in myxoedema, although the production of the thyrotropic hormone in this disease is abnormally increased. This may serve as additional evidence against the unreserved application of animal experiments to human pathology. On the other hand, the posterior lobe is known to produce an antidiuretic factor, and since this is passed straight into the liquor of the third ventricle, the possibility of its contributing to the production of ophthalmic manifestations through water retention might at least be taken into consideration. Marine assumes that in addition to the anterior pituitary the gonads play an important part in the production of exophthalmos. For example, castration of male rabbits caused an existing exophthalmos to regress; the administration of testosterone propionate to the same rabbits caused the exophthalmos to recur (Marine, 1938). As to the relation of androgens and water metabolism, the fact was pointed out by Mulvany that the capon's comb inflates in response to androgens, presumably owing to rise of its water content. The relation of oestrogens to water metabolism is well known and need not be gone into here (see Zondek, *Diseases of the Endocrine Glands*, 1944, p. 53). The fact that in certain cases the exophthalmos rapidly deteriorates after removal of the thyroid, so that finally malign exophthalmos develops, may be at least partly explained by the following hypothesis: thyroidin is known to have a dehydrating effect; thus after its elimination a factor causing water retention will obtain dominance.

In brief, it may be said that the cause of so-called thyrotropic exophthalmos in man is not yet definitely known. Our cases make it appear probable that this type of exophthalmos is part of a complex disturbance originating in the pituitary-diencephalic centres. It is still open to doubt whether in the individual case one or more diencephalic centres or one or more pituitary hormones respectively ought to be considered as the primary seat of the disorder. We therefore raise the question whether these cases would not be more properly covered by the name of "pituitary-diencephalic" exophthalmos so as not to anticipate any undue conclusion. It is worthy of note that Daniels (1938) also attributed the type of exophthalmos described in this paper to diencephalic disorders.

Therapeutically, all three patients received an average of 200 to 300 mg. of di-iodo-tyrosine a day for two weeks, at three-weeks intervals. Two additionally had irradiation to the pituitary. Di-iodo-tyrosine apparently had a beneficial effect, although it cannot be stated with certainty how great a part of it has to be attributed to the irradiation. Thyroidin administration, which would appear plausible in light of the above argument, was in fact recommended for post-operative exophthalmos by Gasteiger (1931) and Mulvany (1944). In any event, it is noteworthy that in Case I medicinal treatment alone brought any considerable regress of the exophthalmos. It should also be noted that in Case III dehydration through a mercurial diuretic resulted in at least subjective improvement of the eyes. In the same case relief of the intra-orbital pressure through partial removal of the orbital roof (Naffziger), which for quite a time appeared the only possible way to safeguard the eye, was rendered unnecessary by medicinal treatment and local protective measures.

Summary

Three cases of exophthalmos are recorded which, according to the present classification, would have been designated as thyrotropic exophthalmos. The ophthalmic manifestations were of particularly severe degree in all these cases. Two of them presented marked decalcification of the skull bones and enlargement of the sella turcica; this finding points to involvement of the pituitary-diencephalic region. Both cases had diabetic glucose-tolerance curves. The abnormally high blood cholesterol level in two cases argues against hyperthyroidism. All three cases favourably responded to di-iodo-tyrosine. In one case (post-operative exacerbation of the exophthalmos) di-iodo-tyrosine, in combination with pituitary irradiation on two occasions, resulted in considerable improvement of the eyes (regress of proptosis, disappearance of chemosis and epiphora, etc.), and thus rendered surgical intervention unnecessary. In view of the fact that the part played by the thyrotropic hormone in the production of this type of exophthalmos is doubtful, while that of the pituitary-diencephalic system seems to be highly probable, the looser definition of "pituitary-diencephalic" exophthalmos is suggested.

HEPATIC ENLARGEMENT WITH ASCITES IN CHILDREN

BY

A. L. McFARLANE, M.B.Lond., F.R.C.S.Ed.

AND

W. J. BRANDAY, M.R.C.S., L.R.C.P.

For many years cases of abdominal enlargement in coloured children in Jamaica, due to ascites and an enlarged liver, have attracted attention, but the aetiology of the condition remains uncertain. It closely resembles the disease among Indian children described by Sir Upendranath Brahmachari (1938), and called infantile hepatic cirrhosis. In our experience the fatal outcome is not so common, perhaps because the condition is not entirely the same or the cases seen by us are in an earlier stage. No cases of the acute type described by Sir Upendranath occurred in this series. The descriptions given by other observers known to us vary, but all are agreed that ascites and enlargement of the liver are present in every case. One member of the staff states that he observed five of these cases some years ago, and all were cured by a generous diet and improved living conditions; he followed them up for a period of over two years. Another member states that he has seen many of these cases and that in his opinion the majority are fatal sooner or later.

Report on a Series of Cases

This paper is based on a series of 18 cases observed by u over a period of about a year; of these 15 have been followe up for six months or longer, and two patients were found t have died, apparently of this disease. There were 11 males an 7 females, but this series was too small to warrant conclusion as to the sex incidence. The illness is a chronic one, beginnin between 1 and 10 years of age, usually in children who unti then had been well. It lasts for months or years, and in ou experience has ended in recovery in the majority of cases though other observers have had contrary results. The histor given is that the illness begins usually with fever, which may b intermittent, lasting for days or weeks, and is accompanie or followed by painless abdominal enlargement, of slight o moderate extent, which may progress slowly or rapidly, finall being greatly increased in size. Loss of appetite, nausea o vomiting, and irregularity of the bowels have been common, an in some cases paracentesis had been performed on one or mor occasions, with temporary relief, but with reaccumulation of th fluid in a short time. Slight jaundice is not uncommon, an the skin is dry and scaly, sometimes shiny, but never wrinkled there is no tendency to other skin diseases. Umbiblical herni occurs, probably because of the increased intra-abdominal pressure; oedema of the legs is rare. Shortness of breath frequently occurs, owing to mechanical interference by the enlarged abdomen. When first seen the tumid abdomen, wasted arms and legs, drawn facies, with bright but rather sunken eyes, the conjunctivae of which are sometimes stained a faint yellow colour, all give the child a striking appearance, which is easily remembered and readily recognized.

The disease is not familial, and probably not hereditary, as no history of its occurrence in any other member of the family or in the parents has been elicited; but the history beyond the immediate past is often undependable, and it is possible that some of the parents had suffered from the disease in infancy or childhood and had long forgotten.

The economic position of the majority of these patients is below the average, and investigation has shown that their diets not only are insufficient in quantity but are largely composed of carbohydrates and markedly deficient in meats, animal fats, and fresh fruits and vegetables. With one exception all the cases came from the poorer parts of the city of Kingston, and instances of this disease had not been noted by us in the rural parts of the island in which we worked for some years.

Clinical examination is essentially negative; only in the abdomen are positive signs discovered. The conjunctivae may be stained with bile, and the vessels may be pale owing to moderate anaemia; the teeth are usually good and the tongue remarkably clean. Enlarged and septic tonsils and adenoids, and cervical adenitis, are not more common in this group of children than in any other. Physical signs in the chest are usually normal; in a few cases a haemic murmur may be present or a few crepitations may be heard at the bases of the lungs. There are sometimes enlarged veins on the anterior abdominal wall; an umbilical hernia is not often present. The marked abdominal enlargement—due to free fluid and the enlarged liver, which were found in every case—made it impossible to decide which had preceded the other. The liver varied in size from one the edge of which was palpable only on deep inspiration to one which extended as far as or below the umbilicus. It was smooth and firm on palpation and not tender, and in several cases the left lobe appeared to be proportionately more enlarged than the right. The size of the liver varied, often rapidly, from time to time, but always remained palpable; the ascites varied in quantity with the size of the liver. In some cases the spleen was also enlarged, but as a rule only moderately. The quantity of fluid present varied, but was usually considerable, and as much as 100 oz. was removed at one tapping. The kidneys appeared to be unaffected, and there were no abnormal signs in the nervous system. The legs and arms were thin and weak, but all muscle groups seemed to share equally in the weakness and wasting.

In Table I the principal signs and symptoms are listed to show the frequency with which they were found in the present series of cases.

TABLE I

Sign or Symptom	Cases Examined	No. Found Positive
Abdominal enlargement	18	18
Hepatic enlargement	18	18
Ascites	18	18
Splenic enlargement	16	7
Jaundice	18	7
Fever	18	18
Dyspnoea	17	5
Umbilical hernia	16	2
Haematemesis	18	1

No cases of acute type were seen; all were subacute or chronic, and were observed for months without any marked deterioration in their condition becoming apparent, though periods of improvement and regression were common. The febrile attacks were usually short, lasting for a week or 10 days, and they occurred more often in the subacute type of case, in which a rise to 103° F. was seen and the child had the appearance of being seriously ill.

Chronic cases may be afebrile throughout their course, and usually after their acute onset pyrexia is not common unless an intercurrent disease supervenes. The chief feature of the illness is the painless and marked enlargement of the abdomen, which finally is so great that it brings discomfort and respiratory embarrassment, with an increased pulse rate; it may be the cause of the loss of appetite and vomiting. Paracentesis gives relief: at first it may be necessary every other day; later the child may be comfortable when tapped once or twice a week; and finally tapping becomes unnecessary. In fatal cases death is usually due to intercurrent disease, often a respiratory infection: one child died in hospital; the post-mortem findings of this case are given below.

Table II comprises a list of the special investigations made in order to throw light on the aetiology of the condition. In some cases it was not possible to carry out all investigations, because of the short time the patient was in hospital, the patient's condition or age, or unwillingness of the parents to consent.

TABLE II.—*Laboratory Investigations*

Pathological Findings	Number of Cases Examined	Number with the Finding	Number without the Finding
Moderate anaemia	18	13	5
„ leucocytosis ..	18	16	2
Low plasma proteins	10	9	1
Kahn negative	15	14	1
Urinalysis normal	15	15	0
Van den Bergh direct positive	13	3	10
„ indirect positive	13	8	5
Sedimentation rate increased	8	8	0
Fragility normal	12	12	0
Blood urea normal	7	7	0
Blood sugar normal	7	7	0

The findings of the single post-mortem examination were largely negative, as pathological changes were observed only in the lungs, liver, and spleen. Congestion and oedema were present in the lungs, but no areas of bronchopneumonia were found. In the liver there was a fine cirrhosis of pericellular type resembling Hanot's cirrhosis, with areas of subacute hepatitis, in which the liver cells showed cloudy swelling and degeneration. The spleen was somewhat fibrosed. In one case an exploratory laparotomy was performed, and it was found that the omentum had lost its fat and was made up of large blood vessels, chiefly veins, in a fine membrane of fibrous tissue. These vessels were adherent to the abdominal wall, and appeared to be acting as an alternative route for the return of blood from the abdominal viscera, in place of the partially occluded portal circulation.

Discussion

The condition is undoubtedly one in which the liver has been damaged. Its rapid enlargement and subsidence suggest an acute inflammatory or toxic condition—that is, a hepatitis—but the source of the toxic agent is not certain. That the disease is infective in nature is supported by the increased sedimentation rate and the fever, and by the recovery of most cases, presumably when the infection had come to an end. The occurrence of ascites only, without dropsy of the limbs, suggests obstruction of the return of blood through the liver, and the low protein content of the ascitic fluid is in favour of an obstruction and not of inflammatory changes in the peritoneal membrane itself. The enlargement of the left lobe of the liver suggests that the site of origin of the toxic agent, if one exists, is in the stomach or spleen—probably in the former, because splenic enlargement is not constant. The toxic agent is not known: it is suggested that the patient's diet, which has been deficient for a considerable time, has reduced the natural resistance of the gastric or duodenal mucous membrane, on which an infection has established itself, and from which toxins have been derived and have damaged the liver, causing its enlargement.

The evidence in favour of a dietary deficiency as the primary cause of the disease is: (1) It is known that the diets of the class from which the patients in this series are drawn are frequently inadequate and unbalanced, and mechanically irritating material is often given to infants or young children: these patients received an even more unsuitable diet than most persons of this class. (2) A balanced and generous diet, alone, produced an improvement which in some cases was marked. (3) The administration of glycocoll in one case appeared to bring marked improvement, which ceased when it was withdrawn. (4) Another member of the staff once observed that improvement in the diet and hygienic conditions brought about an apparent cure in five cases.

The syndrome may be produced by toxic damage of the liver cells, resulting in chronic hepatitis or cirrhosis, or the toxin may cause inflammation or thrombosis of the portal vein, resulting in narrowing or occlusion; the most likely position would be in the smaller radicles. The obstruction and possible damage to the portal vein may also be responsible for the low serum protein, through failure to absorb part of that ingested from a diet already protein-deficient.

Treatment

In three cases special treatment was tried: two were given a concentrated preparation of vitamin B_1 without success; one case appeared to improve remarkably during administration of glycocoll, but relapsed when the treatment was stopped. In all the others only general supportive treatment with rest and a full diet was tried, with some improvement in a few of them.

In a small number of cases seen after this series had been treated dried yeast was administered in doses of 6 or 8 dr. a day with striking results: all improved, and two cases were apparently cured in a few weeks. The explanation of this result is uncertain. It may have been due to the vitamin B complex, in which yeast is rich, or to replacement of protein, of which yeast contains over 40%.

Summary

Cases of hepatitis of unknown aetiology are described. It is possible that they are caused by a dietary deficiency, permitting easy damage of the gastric or duodenal mucous membrane, which becomes infected; the toxin absorbed from this focus damages liver cells or the portal vein, or both, resulting in phlebitis and finally cirrhosis, causing obstruction and partial failure to absorb a particular food constituent from a diet already deficient in that respect.

We would like to thank the Hon. Major T. J. Hallinan, Director of Medical Services, for permission to publish this paper, and other members of the Medical Services for their help.

DARK-ADAPTATION STUDIES IN PATIENTS WITH DISEASES OF THE SKIN

BY

ARTHUR PORTER, M.D., M.R.C.P.

AND

E. W. GODDING

It is well known that an adequate supply of vitamin A is essential for the formation of normal epithelial structures. The basal cells are not apparently affected, and the keratinized epithelium resulting from deficiency of vitamin A is soon replaced by normal cells when the vitamin is given in sufficient quantity. Marked deficiency, whether occurring naturally or experimentally, produces characteristic changes in the skin, the earliest signs being roughness and dryness developing into phrynodermia and follicular hyperkeratosis. These changes are well known, and have been fully described (Bicknell and Prescott, 1942a; and many others). It is possible that slight or moderate deficiencies, though insufficient to produce observable changes in the skin, might render it more liable than usual to the development of dermatitis and infective and other disease conditions generally. It was considered interesting, therefore, to examine the correlation between vitamin A nutritional status and the incidence of skin diseases.

There appear to be only two methods which are likely to yield the required information: blood vitamin A estimations and dark-adaptation measurements. The former of these methods was used by Cornbleet, Popper, and Steigmann (1944), who estimated the plasma vitamin A and carotenoids in 55 dermatological cases and compared the levels with those found in controls. Vitamin A was above the lower normal limit in all, but low levels were present in one case of pityriasis rubra pilaris and two of disseminated lupus erythematosus.

The information obtainable from blood vitamin A and carotenoid estimations is at present limited by the technique employed. Such estimations as are usually carried out provide little evidence beyond the subject's ability to absorb vitamin A and carotenoids from the intestine, and a development in technique (e.g., serial estimations during a test period on a deficient diet) is clearly required if information is to be obtained regarding liver storage capacity. A refinement in technique is also required (e.g., estimations to be made in relation to time and content of a controlled diet) if the present so-called "normal" range of values is to be reduced to useful limits. Such development and refinement in technique would seem to be of importance, since clearly some reduction below a normal blood vitamin A level would be necessary before vitamin A nutrition of the tissues can suffer—unless, of course, the defect is one of tissue utilization.

A combination of blood vitamin A estimations and dark-adaptation measurements has useful possibilities, but first a correlation must be established between the two methods. At the moment Yudkin (1941a) considers estimations of blood vitamin A valueless for diagnosing mild deficiencies.

Dark-adaptation measurements have been used successfully to evaluate the vitamin A nutritional status of groups of people (e.g., Kohn, Milligan, and Wilkinson, 1943), it being usual for the diagnosis of A deficiency to rest upon a significant change in adaptation following the administration of the vitamin. Moreover, the changes in dark-adaptation are regarded by the majority of workers to be the earliest observable sign of a deficiency (see Bicknell and Prescott, 1942b). In the absence of a therapeutic test the results are clearly less reliable, since the causes of impaired dark-adaptation are many (Godding, 1945).

It was not possible to complete the therapeutic tests in the present investigation, but as there was no significant difference between the two groups in respect of age, ametropia, and social status, and as certain other known causes of poor dark-adaptation had been eliminated from both groups, it was thought highly probable that any discrepancy between the dark-adaptation measurements in the two groups would reveal mainly differences in metabolic and nutritional status, vitamin A being included as probably the main factor concerned.

The Investigation

A group of skin cases was provided by the out-patient department of St. John's Skin Hospital and a control group by friends of patients attending the near-by Royal Dental Hospital. Approximately 100 subjects were tested in each group. The skin condition required was a lesion not associated with parasitic infections—e.g., scabies; otherwise, the cases were taken as they appeared. The 103 cases tested were made up as follows: acne (var.) 7, alopecia 7, boils 1, cheiropompholyx 1, Darier's disease 1, dermatitis (var.) 44, eczema (var.) 16, Fox-Fordyce disease 1, impetigo 1, keratosis folliculosis acneformis 2, leuconychia 1, lichen (var.) 3, lupus erythematosus 1, mycosis pedis 1, pityriasis rubra pilaris 1, plantar wart 2, psoriasis 5, pust. bacteride 1, urticaria 3, varicose ulcer 1, seborrhoea 1, sycosis barbae 2. It will be observed that dermatitis accounts for nearly 50% of the cases.

From both groups the following were excluded: subjects under 16 and over 45, subjects with uncorrected refractive errors of less than 6/24 either eye, obvious muscular defects (e.g., squint), opacities of the media and ocular disease conditions generally, subjects with a history of general disease conditions, particularly gastritis, gastric and duodenal ulcer, liver

Table I.—*Comparison of the Test and Control Groups*

	Total	Sex		Age			Average Age	No. Wearing Glasses	No. with Uncorrected Vision less than 6/6 (R. or L.)
		M.	F.	15–25	26–35	36–45			
Skin cases	103	49	54	27	45	31	29·8	13	22
Controls	101	34	67	50	33	18	26·9	14	15

dysfunction, and recent infection. Pregnant and nursing mothers were also excluded.

The apparatus used for the dark-adaptation test was that described by Yudkin (1941b), with the addition of a means of stabilizing the voltage. The procedure was as follows:

Method.—Each subject was generally examined as indicated above, and the test explained and demonstrated. They were put into the dark-room at 10-minute intervals. Before entering the dark-room no subject had been in the hospital less than half an hour, to safeguard against the effects of exposure to previous high brightnesses (Craik and Vernon, 1942). At the end of the first subject's 30 minutes' dark-adaptation time the test was made, and so on with the remainder at 10-minute intervals. By this arrangement the intervals between subjects entering the dark-room and being tested were balanced so that all were dark-adapted for 30 minutes. The test object (arrow) was first shown at a brightness which could be seen fairly easily, and the brightness decreased until the threshold reading was obtained. The test was then continued to 40 minutes. As under the conditions of the test the expected difference between the readings at 30 minutes' and 40 minutes' dark-adaptation time is not more than 0.1 μμl log unit, subjects showing greater amounts than this were re-tested. In addition all readings of 3.83 μμl log units and over were confirmed. The threshold measurements of brightness seen at 30 minutes' dark-adaptation time expressed as log μμl were those taken.

The measurement of dark-adaptation by means of such "final" threshold measurements, while not yielding the same amount of information as can be obtained by a "full" test, is nevertheless the most useful single measurement which can be taken (Yudkin and Robertson, 1943), since it has been shown that the threshold measurements at 30 minutes' dark-adaptation time are always affected if dark-adaptation has been impaired through lack of vitamin A. The results are shown in Table II.

TABLE II

	Total No.	Threshold Reached, Logμμl, at 30 minutes, D.A. Time							Mean Threshold Logμμl
		3·40	3·53	3·72	3·84	3·93	4·01	4·14	
Skin cases	103	8	45	32	10	2	5	1	3·679
Controls	101	8	36	39	14	1	2	1	3·683

Comment

There is thus no significant difference between the mean threshold values of the two groups. The values obtained seem to be rather high (cf. Yudkin, 1941c), although these absolute values should be accepted with some reserve, as the standardization of the instrument has not been checked for some time.

Two cases of particular interest appeared in the skin group—one a case of Darier's disease and the other a case of pityriasis rubra pilaris; the latter, which has been fully reported elsewhere (Porter and Godding, 1945), responded to vitamin A therapy, and good correlation was established with the dark-adaptation results. The former will be discussed along with other cases of Darier's disease in a further paper.

Summary

A dark-adaptation test revealed no significant difference between a group of skin cases and a group of controls.

It is highly probable that with the safeguards applied the results ndicated a similarity in vitamin A nutritional status between the wo groups.

We have to acknowledge with thanks the co-operation of the oard of management and administrative staff of the Royal Dental Hospital in providing the facilities which enabled us to carry out he tests on the control group; and to thank the Crookes Laboraories for the loan of the dark-adaptation apparatus and for generous upplies of vitamin A.

Medical Memoranda

Tubercle Bacilli and Urea

In the *Journal* of May 16, 1942 (p. 609), I recorded in a short paper the bactericidal action of urea in saturated solution on an equal volume of a strong suspension of human tubercle bacilli in distilled water—the resulting mixture containing, of course, a half-saturated solution of urea. In July, 1944, I had the pleasure of receiving a letter from Dr. R. M. Humphreys, late senior physician, Sudan Medical Service, stating that he and his assistant, Dr. Abdel Halim of the Khartum Civil Hospital, had had good results in treating a local civilian with (*a*) dry powdered urea on the skin ulcerations resulting from infection of the needle-tracks from a tuberculous pyopneumothorax, and (*b*) the use of a half-saturated urea solution as a replacement fluid in the same patient. The ulcers healed quickly under the urea powder, and the fluid, after eight removals, washings-out with sterile saline, and replacement with 300 c.cm. of half-saturated urea solution, became at last completely sterile for tubercle bacilli. It is to be noted, too, that the washings of the first fluid introduced, though found to contain many acid-fast bacilli, were sterile from the point of view of culture.

This communication recorded such favourable results and seemed so much what I had expected that I decided to make a few more experiments with urea; these are here set forth:

Three cultures—human, bovine, and avian—were obtained from the National Collection of Type Cultures, and subcultures were put up with saturated urea solution, the method being identical with that previously described. In the course of a month all three exposed to the saturated urea solution remained apparently sterile. There was a growth of tubercle bacilli on the "second dilution" capsules, except in the case of bovine tubercle, and in all lesser concentrations. The controls, of course, grew well. At a subsequent subculture from the apparently sterile capsule of human tubercle bacilli a very small growth was obtained—a fact which led to a further trial with the use of a more carefully saturated urea solution. On this further trial the saturated solution + t.b. was typically negative for tubercle bacilli both on the original capsule and on subculture.

It would seem that strains of tubercle bacilli vary somewhat in their sensitivity to urea. It may be added that the fluids containing saturated urea and t.b. and the controls containing only t.b. were inoculated into guinea-pigs and that *neither* animal developed tuberculosis. This is curious, as the "control" was positive and should have killed. The strain is being further investigated.

With the assistance of Major Elliott, chemist at the R.A.M.C. College Laboratories, and Cpl. Johnson, R.A.M.C., I made the following further observations: (1) Saturation point is reached with approximately 92.3 g. of urea to 100 c.cm. of distilled water at 19° C. (2) Saturated urea has a *p*H of about 6.8 (brom-cresol-purple). (3) The mould *Penicillium notatum*, suspended in saturated urea, was apparently unaffected. (Control in saline.) (4) A suspension of tubercle bacilli in half-saturated urea solution was divided into two parts. Half was subjected to dialysis, half not, and the two were compared after 48 hours. The result was: undialysed portion, 55.2 g. of urea per 100 c.cm.; dialysed portion, 0.013 g. of urea per 100 c.cm.

It would appear, then, that a strong suspension of tubercle bacilli, killed by 48 hours' contact with a saturated solution of urea, can be freed of urea by dialysis and retained as a dead bacterial suspension for any purpose required.

My thanks are due to Dr. R. St. John Brooks of the National Collection of Type Cultures; to Col. F. S. Irvine, C.M.G., D.S.O., commandant of the R.A.M.C. College; to Lieut.-Col. W. R. M. Drew, Professor of Tropical Medicine; and to Major W. A. Young, Major Elliott, and Cpl. R. I. Johnson, R.A.M.C., for invaluable help.

S. LYLE CUMMINS, C.B., C.M.G., M.D.

Recurrent Ectopic Gestation on the Same Side as Previous Salpingectomy

The case reported here may be found to be of interest not only because of its rarity but also because, if the possibility of recurrence is recognized, the chances of this unfortunate accident occurring may be lessened at the first operation.

CASE HISTORY

The patient, a woman aged 35, her occupation at the time being welding, was admitted to Tilbury Hospital on April 3, 1944, complaining of lower abdominal pain. The time of onset had been 4 days before; the pain had later become less severe, but on the day of admission had returned with increased intensity. The date of the last menstrual period was Feb. 4, 1944; there had been no vaginal bleeding of any kind since then. Her periods were regular, usually lasting 7 days every 28. She had three children—the youngest 10 years of age—and had suffered from a vaginal discharge previous to the birth of this child.

The history was that the patient had been admitted to the same hospital on Aug. 24, 1933, and operated on for an ectopic gestation on the left side. At the operation she was found to have a pelvic haematoma, with a mass surrounding the left tube and ovary; the left tube and ovary were removed. Recovery was uneventful.

When examined on the present occasion the patient was quite pale; pulse 100, temperature 97.6°, blood pressure 75/60; chest N.A.D. The abdomen was slightly distended, with some rigidity of the lower part and marked tenderness, especially in the left iliac fossa. On vaginal examination there was a muco-purulent discharge but no suspicion of blood. The cervix was lacerated and somewhat soft. The fornices were extremely tender, but the shape and size of the uterus could not be made out owing to abdominal tenderness and rigidity. A tentative diagnosis of ectopic gestation was made, but owing to the patient's history it was decided to watch her for a short period. As after two hours the pulse rate was rising, operation was decided upon, intravenous plasma being given beforehand. Nitrous oxide, oxygen, and ether anaesthesia was employed. The old infra-umbilical scar was excised and the abdomen opened. The pelvis was full of clotted blood. On examination of the uterus the left tube and ovary were found to be absent; the uterus was the size of a 6 to 8 weeks pregnancy. The left cornu of the uterus was eroded and in fact ruptured during the handling of the organ, extruding a small foetus, age 6 to 8 weeks. Owing to the size and nature of the rupture it was found necessary to perform a subtotal hysterectomy. The patient's recovery, apart from a mild tonsillitis, was uneventful, and she was discharged on April 26. Examination of the uterus showed an ectopic pregnancy arising in the intramural portion of the tube that had previously been removed.

Comment

Although cases of recurrent ectopic gestation are relatively common, the literature on the subject reveals very few cases in which the extra-uterine pregnancy has recurred on the same side, and still fewer in which the recurrence followed salpingectomy on the same side. Wetterweld's (1927) case did not have the tube removed in the first instance, and in the case reported by Bracht the recurrence was in the ampullary portion of the tube. Bello *et al.* (1929), Saass (1930), and Nizza (1933) all reported cases of ectopic gestation recurring on the same side as previous surgical intervention, and Scipiades (1934) recorded a case of recurring tubal pregnancy on the same side as previous surgical intervention, with a living child born at term. Apart from these examples, this type of case appears to be a very rare form of accident.

I would like to thank the staff of Tilbury Hospital for their help in compiling this case report.

Tilbury. SIDNEY GEE, M.B., B.S.

JOINT TUBERCULOSIS COUNCIL

The Joint Tuberculosis Council, at its last meeting, discussed several matters of interest to the tuberculosis world. On the recommendation of the Joint Education Committee (upon which the Council and the National Association for the Prevention of Tuberculosis are represented), the Council approved the draft constitution for a Tuberculosis Educational Institute. This institute will arrange courses, lectures, and demonstrations for the education of doctors, nurses, almoners, and social workers in tuberculosis. It will, it is hoped, act as an information centre in all matters connected with tuberculosis education, and will recommend candidates for N.A.P.T. scholarships. The institute will suggest lines of research in tuberculosis, and will generally facilitate and encourage the study of the subject in Great Britain by visitors from over-seas. It will work in co-operation with university postgraduate centres and will give them all possible assistance. The Joint Education Committee also recommended the N.A.P.T. to award two £50 scholarships for health visitors, and two scholarships of similar amount for student almoners. The Council's Committee on Reorganization of the Tuberculosis Services (which at this meeting was renamed the Committee on Development of the Tuberculosis Services) was asked to consider and report upon the present situation in relation to the proposal National Health Service (with particular reference to the recent negotiations between the Ministry of Health and the B.M.A.). The Council decided to approach the Spens Committee with representations that tuberculosis clinicians should be dealt with, in any scheme of salary revision for practitioners engaged in public work, on the same basis as specialists in other branches of medicine.

Reviews

ARTHRITIS AND ALLIED CONDITIONS

Arthritis and Allied Conditions. By Bernard I. Comroe, M.D., F.A.C.P. Third edition, enlarged and thoroughly revised. (Pp. 1,359; illustrated. 60s.) London: Henry Kimpton.

The arrival of a third edition of this important work within five years of its first appearance is ample testimony to the place it has gained in the literature of rheumatic diseases. Advantage has been taken to rewrite some chapters and to bring the whole up to date, and a good deal of fresh matter has been added, increasing the 750 pages of the first edition to 1,359 in this one. The needs of the general practitioner have been studied and a new chapter presents a diagnostic digest of the average arthritic problem; there is also a new chapter on treatment in general practice, while the valuable feature of the first edition of presenting summaries in "box form" so as to be easily available to the individual with little time for reading is preserved.

The sulphonamides are dealt with in the light of the most modern knowledge, and a chapter on penicillin has been added, though its use in arthritic conditions appears to be limited. The chapter on massage has been enlarged with very helpful illustrations, while other forms of physiotherapy are fully described, enabling the practitioner to prescribe exactly what he wishes to be done instead of leaving it to the masseuse, as is so often the case. One of the most striking features is a chapter on mistakes in the diagnosis and handling of patients with arthritis and allied conditions, which will be read with profit by the most experienced workers in this branch of medicine. The possible mistakes number 238, a formidable array, and it is a temptation to quote some of the most striking; but one deserves the attention of our rulers and governors whose attention may be drawn to it, since it is unlikely that they will come across it otherwise. "Mistake 63 is the lack of sufficient funds for investigative work and lack of adequate hospital facilities for the care of arthritic patients." It is pointed out that in the U.S.A. there are not more than 200 free beds for rheumatic cases as compared with 100,000 for tuberculosis, though arthritis and allied complaints are more common than the sum of all tuberculosis, cancer, diabetes, and heart disease.

HUMAN AND ANIMAL PARASITOLOGY

Introduction to Parasitology, With Special Reference to the Parasites of Man. By Asa C. Chandler, M.S., Ph.D. Seventh edition. (Pp. 716; illustrated. $5.00 or 30s.) New York: John Wiley and Sons; London: Chapman and Hall.

This book has grown considerably since its original appearance over twenty-six years ago. Its title has been changed several times to meet its increasing scope, and now it reaches the seventh edition four years after publication of the sixth. The book is thoroughly up to date, and anyone who wishes to obtain a comprehensive view of human and animal parasitology can hardly do better than secure a copy and read it carefully from cover to cover. The author has kept himself informed of the many advances in knowledge in the fields of protozoology, helminthology, and entomology which have been made during the war, and has incorporated all of them. Thus, to name only three of the new additions, mention is made of the trypanocidal action of aromatic diamidines, of the successful transmission of lishmania infections by the bite of sandflies, and of the remarkable insecticidal properties of D.D.T., particularly with reference to its effect on the louse and the influence this has on the spread of typhus fever.

The main descriptions in the book relate to the parasites of man, but sufficient information is given of parasites of animals to make it of use to veterinarians as well as to medical men. Short accounts of spirochaetal, rickettsial, and virus diseases are included. There are no coloured plates in the book, but the black-and-white illustrations, of which there are over 300, are adequate. Systems of classification are not over-emphasized, and when inserted are in smaller type arranged in such a way that they can be disregarded by the reader who is not particularly interested in this branch of the subject. It seems unnecessary to say anything more about the work. It is a good one which can be thoroughly recommended.

THE PREMATURE BABY

The Premature Baby. By V. Mary Crosse, M.D., D.P.H., M.M.S.A., D.R.C.O.G. Foreword by Leonard G. Parsons, M.D., F.R.C.P., F.R.C.O.G. (Pp. 156; illustrated. 10s. 6d.) London: J. and A. Churchill. 1945.

This excellent book has been written by Dr. Mary Crosse from her extensive and intensive study of the problem over the past fourteen years at the special unit in the grounds of one of the maternity homes of the city of Birmingham. In recent times it has become increasingly known that the results being obtained at this unit were extraordinarily good, and all concerned with the care of the newborn will be grateful for having the details of how this has been achieved set out so clearly and with such confidence. Dr. Crosse deals with how the premature baby should be managed not only in hospital but also in the home. Essentially the methods adopted are simple and practical—so far as it is possible to simplify what can often be quite a complicated procedure. In thirty pages Dr. Crosse tackles the complex programme of feeding, and a small criticism of this section is that the harassed practitioner who has to arrange for the artificial feeding of a premature baby is given plenty of choice but little direct lead. A concluding chapter on general statistics and an appendix with the Birmingham figures sum up the whole matter. As Prof. L. G. Parsons says in his foreword, the results under Dr. Crosse's skilful guidance have so far been unrivalled in this country. Their successful imitation would represent a substantial saving of life in the newborn period. There is othing set out in this book which could not be done by other uthorities.

Notes on Books

The horrible fact that so many children have been found in the oncentration camps in Germany and the countries liberated from German oppression lends added point to the reprint of a pamphlet, ublished last year by the Ling Physical Education Association, on he *Use of Exercise in the Post-War Rehabilitation of Children in Occupied Countries* (Hamilton House, Bidborough Street, W.C.1; rice 2s., postage 3d.). The compilers of this pamphlet advisedly ook an objective view of the probable conditions contingent on German evacuation, and, like the members of the Parliamentary elegation who visited the Buchenwald camp, regarded intentional understatement as the most telling way of bringing home the horror of the Nazi regime. The report is based on the expert medical and ducational knowledge of people who have seen the effects of malnutrition on children. After its original publication lectures and lasses, based on its teaching, were given to teachers and volunteers f many different nationalities, including groups from the Czechoslovak Social Welfare courses, the British Council's course in Social Welfare for Allied Nationals, the Society of Friends, the French .T.S., the Ling Physical Education Association, and the International Women's Service Groups; and instruction was given in he types of defects most likely to be seen among malnourished hildren, and in graded physical activities likely to benefit those whose condition did not necessarily warrant immediate admission o hospital. The pamphlet includes general considerations to be bserved in the physical re-education of the children, the sources f teachers likely to be available, and a chart of defects and eformities resulting from starvation.

Aids to Psychiatry is the fifth edition of Prof. W. S. DAWSON'S tle book in twenty years—a tribute to its popularity with students nd practitioners. Admittedly severely concentrated and, of course, places sketchy, this edition has been brought up to date and covers practically everything about the psychoses, psychoneuroses, nd amentia which is commonly required by the non-specialist. etails are not given of specialized treatment such as the presently opular shock therapy or of psycho-analysis, but they are mentioned, which is all that is required for those who cannot and ought not to ndertake such treatment. There is a useful chapter on differential agnosis in certain symptoms and syndromes, and finally a short hapter deals with what mental hygiene and child guidance are doing the field of prevention. The book is of pocket size and may be ofitably dipped into in leisure moments. It is published by aillière, Tindall and Cox at 6s.

The seventh edition of T. J. MACKIE and J. E. MCCARTNEY'S *andbook of Practical Bacteriology* (E. and S. Livingstone; 17s. 6d., lus 7d. postage) differs little in the main from its predecessor, the uthors having adopted the convenient method of incorporating ew material in an appendix, which now extends to 43 pages. In bench-book this has something to recommend it, since the customed user then finds all descriptions of new methods assembled one place.

Preparations and Appliances

ENDOMETRIAL BIOPSY CURETTE

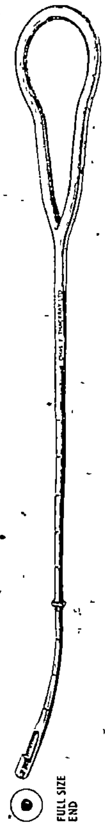
Mr. LINDSAY O. WATT, F.R.C.S.Ed., assistant honorary surgeon to the Derbyshire Hospital for Women, writes:

This endometrial biopsy curette has been designed with several added features to give information in sterility investigations. The instrument has a total length of 10½ in. and is constructed with a shaped handle to permit a firm and comfortable grip. The neck of the instrument is curved to allow more easily the curettage of the anterior wall of the uterus. The specially designed cup is as short as possible, allowing a biopsy to be taken from close to the fundus of the uterus, and so give a much larger and longer strip of endometrium for histological section. The large sharp prominent edge of the curette cup enables one more often to get a sample of atrophic endometrium, as in menopause or epimenorrhoea, where obtaining endometrium is often difficult.

The head of the curette is large and the end is rounded, the overall diameter of the cup being 3/16 in. The design is such that the minimal compression of the biopsy guarantees the least distortion (size and shape of the glands) in the ensuing histological picture. The shape of the groove proximal to the cup facilitates the extraction of the specimen from the curette.

The notches at 1/2-in. intervals graduate the instrument to a total distance of 5 in. from the distal end, the first notch being placed at a distance of 1 in. from the end; a node is also placed at 2½ in. from the end of the curette. When the curette is inserted into the nulliparous cervix the head of the instrument is arrested at the internal os. In this way the length of the cervical canal can be measured. In the anteverted or/and anteflexed uterus slight forward curving movement of the curette easily passes it through the internal os into the corpus of the uterus. By passing the curette up to the top of the uterine cavity the corpus of the uterus can be measured and its relation to the cervix (infantile, etc.) can be estimated.

In some anteflexed uteri of infantile type it is occasionally necessary to dilate the internal os with a 3- or 4-mm. uterine sound before passing the curette from the cervical canal through the internal os, otherwise slight difficulty may be experienced in removing the curette from the corporeal cavity.



One would advise that the quadrant from which each sample is taken should be noted on the patient's case paper. If several samples of endometrium are taken at weekly intervals biopsies repeated in error from the same site will give a fallacious result due to the regenerating endometrium.

The instrument is now available in stainless steel and is manufactured by Charles F. Thackray Ltd., Park Street, Leeds.

LIVER EXTRACT FOR INJECTION

"Wellcome" injection of liver extract is stated by Burroughs Wellcome and Co. to be prepared by a special process designed to conserve the therapeutically active principles of liver while eliminating inert or antigenic substances. It contains a full representation of the components of the vitamin B complex normally present in liver. Each batch is tested clinically before issue and the strength is apparently of the order of 2 units per c.cm. Many clinicians prefer a liver extract of this type, in which the haematinic principle is not too highly purified or separated from other potentially active fractions of the liver.

A third group of Belgian professors representing the Belgian Fondation Universitaire is now visiting Britain for a fortnight at the invitation of the British Council. They are meeting British scientists and medical men and are visiting universities or research institutions in London, Reading, Oxford, Cambridge, Newcastle, Aberdeen, Edinburgh, Liverpool, and Greenwich, and the I.C.I. works at Billingham. The delegates are: Dr. F. H. Van den Dungen, professor of science and applied science at the University of Brussels; Prof. A. E. Michotte van den Berck, Faculty of Medicine (Experimentary Psychology), Louvain University; Prof. A. E. Gratia, Faculty of Medicine, Liége University; Prof. J. A. H. Rodhain, Director of the Institute of Tropical Medicine, Antwerp; and Prof. E. J. M. P. Mertens, Faculty of Science, Louvain.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JUNE 16 1945

RETURN FROM STALAG

It is one of the paradoxes of the day that release and reaction from the emotional tension of war may for some time lead to more rather than less difficulty in human affairs. The first large groups of Service men to be repatriated are prisoners of war from Germany; and while the proportion of those who have suffered serious organic damage is less than it might easily have been, the problems of resettlement likely to be presented by returned men in general are illustrated only too clearly by the difficulties of these repatriates and their families. In clinical work, in discussion with friends, and in casual conversation, it is borne in upon the doctor that years of life over-seas produce changes in men, and indirectly in their families, from which recovery is neither immediate nor easy. The returned men themselves remark, sometimes with dismay, that we in this country are strange and that we do not seem to understand the effects of war on human personality. On the other hand, wives and families say that returned men are preoccupied and uncertain and that it is difficult to predict their reaction to various plans made to please them. These are the inevitable results of the reunion of two groups who have been leading widely different lives. The experience, the outlook, and the ways of each group differ, and there is an inevitable period during which the plans and expectations of the repatriate and of those at home move out of the world of dreams in which they have lived during the years of separation and are brought together on a basis of reality.

The fundamental difficulty from which repatriated Service men suffer appears to be an incomplete assimilation of the discovery of human insignificance in the face of external dangers and powerful internal emotions. There is nothing particularly extraordinary in the discovery, for most people are compelled to make it at some time in their lives, even in peacetime; but in war the discoveries crowd fast upon us, and many variations of this same theme are presented in a short space of time. From the moment the soldier joining his regiment discovers the intensity of feeling with which he misses his companions his life enforces the same lesson. The prisoner of war learns with poignant force at the moment of capture, and during the immediately succeeding period, that his identity as a person is of no significance; he is only one more body. It is only too clear to him that if his guards cannot be bothered with him they can rid themselves of an incubus by shooting him and reporting that he tried to escape. He realizes that others can contemplate his fate with the same frigid detachment with which in the past he himself has read, say, of famine in China. It is from these deep springs that there arises the common complaint of repatriated men that they are "not wanted." The real point is that a cold and dispassionate Fate does not want any of us in the paternal and affectionate way we somehow expect.

The prisoner of war lives for months or years in an environment which is hostile or indifferent, except for those people who share his fate with him. During this period he has also to realize that the lessons of civilization seem to have been learnt only on a superficial level. It is common to hear a returned man say that the behaviour of a few of his fellows was incompatible with what might be expected, for example, of an officer. He will talk of pettiness, of thefts, of lethargy, all as matters of surprise. We may be sure that he has been equally surprised by the power and intensity of similar feelings in himself, and this at a time when his "self" has been displayed as a being of little or no moment. With slight variations the same can be said about those soldiers who have not been taken prisoner. Lord Moran has described the deterioration following on the continuous expenditure of spirit in war. There is no doubt of the accuracy of this picture; the important thing is that the expenditure arises not only from the need to meet external dangers but from the need to tolerate the existence of internal turmoil which seems to have no other controlling force than the "self" which is so discredited in its owner's eyes that he feels it is totally incapable of its task. On return to this country the soldier meets many people whose self-esteem has suffered no diminution comparable with his own. He feels that he knows more about life than those of us who have been at home, but he also feels a crippling lack of confidence which we at home do not appear to feel. As a result he thinks that he recommences civil life at a disadvantage. It may take him many years to recognize and to admit the truth of the lesson that Fate has taught him, for it is hard for any of us to believe that the lesson is a good one to learn. If he learns it he is no longer discouraged by the self confidence of ignorance and immaturity. But before thi point is reached he suffers from a plethora of difficultie which do nothing to further either his self-confidence o his amiability. As has already been hinted, this does no prevent him from insisting that he is "exactly like othe people." And this is natural enough, because he means that other people would be exactly like him if they knew as much about life as he did. Unfortunately, they do not and no amount of unconscious effort on his part to mak them feel as insecure about him as he does about them can produce the equilibrium he desires.

There is no need to go into subsidiary difficulties, suc as over-sensitiveness to frustration, intolerance of loneliness, and intolerance of company, which affect the repatr ated man, and particularly the returned prisoner of wa The important thing is that the physician should grasp perhaps by recalling his own position twenty-five year ago, the all-pervading effect of deep emotional insecurity Nor is it necessary to give a detailed account of the way in which a prisoner of war, denied physical mobility, achieve mental freedom to go where he will, when he will. Th point is that on his return he tends to find real freedom disappointing and frustration-ridden substitute for the freedom he achieved in imagination. Any attempt to "treat" the returned prisoner of war, or any other returned Service man, because he has "symptoms" of this kind puts the physician in an untenable position with regard to the "patient"; but it should not be difficult for these men to obtain the comfort of understanding from a doctor who has seen, and will continue to see, people in the height of their powers, and with the security of material possessions, struck down by disease or domestic catastrophes of other kinds. It should be easy for the doctor to place himself in a sympathetic relationship with Service men who may be suffering from an overdose of such experiences. Medical men do not consider themselves "ill" or "queer" because they belong to one of the few classes who, in ordinary peacetime life, are really aware of, and indeed must accept, the fundamental insecurity of home, possessions, and fame. It should not therefore be difficult to discard any idea of 'illness" when dealing with this aspect of the problems f the returned soldier; and, whatever theoretical views he doctor may hold about such matters, at least the heoretical views need not be obtruded. If he can talk s man to man, encouraging his patient to face life's in-ecurity much as a doctor must, he will be employing sychiatric machinery; but the machinery need not cause rritation by creaking. Any man who cannot be helped long by easy conversation on this basis must be considered ith some care. In many cases acute strain should be isibly dissipated by such superficial methods; if it is not he doctor should see the red light. Emotional disorders xist in peacetime; the air of the Stalag is not so salubrious hat they cannot thrive there as well, and it may be that sychiatric disorders are better handled with the advice of e psychiatrist.

ENAL LESIONS DUE TO SULPHONAMIDES

he chief ill effects of sulphonamide therapy are urinary obstruction, sensitization reactions (fever and rash), and lood changes (agranulocytosis or acute haemolytic aemia). In good American practice the relative fre-uency of these toxic symptoms after the administration sulphathiazole is given as renal calculus in 2.8% of tients, sensitization phenomena in 6.2%, and agranulo-tosis and haemolytic anaemia only in rare cases; ter sulphadiazine renal calculus occurred in 1.5% of the tients.[1] The cause, symptoms, and treatment of urinary struction due to the sulphonamides are now well known. he sulphonamide is filtered off from the blood in the omerulus of the kidney in solution in the glomerular fil-ate; but as this fluid passes down the tubule water is sorbed, until eventually the less soluble compounds such sulphapyridine, sulphathiazole, sulphadiazine, and their etyl derivatives are precipitated as crystals, which cause struction. The blockage may occur in the lower parts the renal tubules, in the collecting tubules, or in the eter, especially at its opening into the bladder. The mptoms of this obstruction are (1) pain, which may be located in the loins and radiate to the groin, or may be felt in the abdomen generally; (2) diminished output of urine proceeding to complete anuria; and (3) macroscopic haematuria. In the presence of any one of these symptoms urinary obstruction should be diagnosed, the sulphonamide discontinued, and steps taken to relieve the obstruction. If the obstruction is incomplete it usually suffices to increase the fluid intake either by mouth or by parenteral infusion and to give alkalis to render the urine alkaline, and thereby increase the solubility of the sulphonamide crystals. But if anuria has persisted for 12 hours, or oliguria (less than 500 c.cm. a day) for 24 hours, an increased fluid intake is harmful, leading to waterlogging of the body, and ureteric catheterization should be undertaken without delay. Urinary obstruction is prevented by maintaining a good flow of urine through ensuring a large fluid intake (6 pints a day), by keeping the urine alkaline (this may require 6 grammes of sodium bicarbonate or more a day), and by watching closely for any diminution of renal flow; this is best arranged for by having the 24-hour volume of urine prominently recorded on the temperature chart.

In addition to the lesions due to obstruction it is sometimes maintained that sulphonamides may cause other renal injuries. In one type of case the renal lesions form part of a more widespread syndrome set up by sensitization of the body to sulphonamides. Sensitization is usually manifested as drug fever or as a sulphonamide rash; when administration of the sulphonamide is stopped the symptoms subside. But in some cases, such as those described by Lederer and Rosenblatt,[2] the pathological reactions progress because the correct diagnosis has not been made or because of factors still unknown, and the patient rapidly goes downhill and dies. Small areas of focal necrosis are found scattered throughout the viscera, including the kidney. The mode of production of these lesions is not clear. Usually there is no evidence that the kidney suffers more severely than other organs, or that the renal lesions have a major responsibility for death when it occurs. Besides these lesions of hypersensitivity, some observers maintain that sulphonamides may cause degenerative changes in the cells of the renal tubules by direct chemical action.[3] Young[4] and Rosenblatt and Grayzel[5] have described marked degeneration of the renal tubules at necropsy of patients who had received sulphonamide drugs for rather obscure conditions. The interpretation of such cases is difficult. The renal lesion might have been due to the original infection for which the sulphonamide was given, or to sensitization; in Young's four cases there was a preliminary (? sensitizing) course of sulphonamide, followed after an interval by a second (? precipitating) course. It might have been due to obstruction by crystals which were dissolved before death. Other observers have described degeneration of the epithelium of the tubules in cases in which urinary obstruction was caused by masses of sulphonamide crystals: the degeneration may have been secondary to the obstruction rather than due to a chemical action of the drug upon the cells. According to Vilter

and Blankenhorn[18] nephrosis due to sulphonamides, though rarer than obstruction by crystalline deposits, is more dangerous, since it is less amenable to treatment. In their series it occurred between the first and fifth days. There are no premonitory symptoms. It may or may not be accompanied by oliguria and/or albuminuria. The most important indication of all is elevation of the blood urea; if this is present nephrosis should be suspected and sulphonamide administration stopped at once; further treatment is palliative, and "heroic" measures should be avoided. Nevertheless all such descriptions of renal degeneration brought about by a direct action of sulphonamides upon the tubules should be regarded with reserve.

THE SENILE OFFENDER

Much is heard in these days about juvenile delinquency, but the problems of the aged delinquent tend to be forgotten. A tardy interest is now being aroused in the medicine of old age, and Dr. W. Norwood East has just prepared the ground for a similar movement towards the study of crime in relation to senescence and senility.[19] The problem, as he shows, is increasingly important, for the percentage of aged persons in the population is rapidly growing. During the ten-year period ending in 1938 nearly 14,000 persons of 60 and over were found guilty of indictable offences. Dr. East's clinical experience suggests that, as age advances, personality seems to become a more important factor than environment in leading to crime. In young and middle-aged persons a first offence is only now and then an early indication of mental abnormality. In an elderly person it should at once arouse suspicion of senile degeneration. Many habitual criminals are not deterred by age from committing crime, and there is almost no upper age limit.

The official statistics throw little light upon the mental background associating crime with senescence and senility. If, however, growing old is as natural a process as growing up and senescence is the counterpart of adolescence, it becomes practically important to differentiate criminal behaviour which is associated with senescence from that which can be attributed to the mental diseases of senility. Criminal behaviour may be due to an unexpected jolt suffered by a tottering personality. Ageing is not always a uniformly progressive and unobtrusive reduction of physical and mental power. A physical illness, grief, or other severe emotional disturbance may quicken mental deterioration. An outstanding evidence of senescence is the failure to exercise the authority of former years. An employer who becomes for practical purposes the employee of his partner may be forced to take part in a fraud without fully understanding its implications and may be left to face the consequences alone. Nowadays the occupations as well as the amusements of aged persons tend to become less social, less varied, more solitary, and more proprietary. Unless the problem of leisure is treated with much consideration the aged person may adopt an undesirable pattern of life, and crime may result from a new habit of relieving tedium by alcohol or some other time-passing appeasement. Just as intellect and emotion deteriorate in senescence, so does the power to will, and hence the power to inhibit illegal behaviour. Senescence passes into senility when the impairment of mental and moral vigour becomes excessive, the mental activities being imperfectly synchronized, and when initiative, judgment, and perseverance fail and social maladjustment results. The practical difference between senescence and senility in criminal cases is measured in terms of social adjustability and the capacity to deal with personal problems as they arise. When an aged person is implicated in criminal proceedings it is well to differentiate senile and arteriosclerotic dementia from other psychoses. This need applies with particular force to the differential diagnosis of the depressive and manic varieties of senility from manic-depressive disease in the aged. Prognosis will largely depend on previous history. In early senile dementia crime is usually trivial, but serious crimes are rather frequently associated with depressive, manic, and paranoid dementia. In depressive cases attempts at suicide are common, and homicide, often altruistic in purpose, is not rare. Hallucinations and delusions often underlie crimes of violence. Sometimes acute or chronic alcoholism is superadded, especially in cases of marital jealousy. The conduct and mental condition of a senile offender should be compared with his own standards of former years as well as with the standards of so-called normal persons.

Dr. East concludes that a knowledge of the mental background of the aged offender may suggest the most suitable way of dealing with him and of protecting society from his misconduct. The modification in his culpability should be considered by the court before sentence. The weaknesses of the aged offender may, he suggests, claim our sympathy if not our respect.

MUSCLE NECROSIS AND INFECTION

A reaction peculiar to a particular experimental animal i a frequent source of fallacy and misleading analogy: later when fully understood, the experimental findings ma be usefully applied to conditions in man. An excellen example of this sequence is given by recent investigations of "shock" in the dog. This animal's tissue characteristically contain clostridia as normal flora. When muscle was excised, crushed, and re-implante under sterile conditions the animals died in what Prinzmetal and his colleagues[2] term "toxic shock." They contrast this with the "extravasation shock" brought abou by local loss of fluid. The former was delayed in onse for many hours, and the local loss of fluid was sligh according to the authors' figures for plasma volume. A necropsy the site of re-implantation was grossly contaminated with pathogenic streptococci, staphylococci, an clostridia. These authors[3] found that if sulphamerazin was inserted locally or administered within six hours "toxi shock" did not appear. Some benefit was obtained eve after seventeen hours' delay, but no protection was seen i treatment was delayed for twenty-four hours. A simila observation was made when removal of the crushed musc prevented the appearance of toxic shock. A finding c some interest is that the concentration of sulphonamid was three times higher in traumatized tissue than in norm muscle. This is difficult to explain, for although the extr cellular phase of muscle, normally about 15%, ma increase after injury to 75% (judged by chloride distr bution in experimental and human crushing injury), sulpl anilamide, like urea, is distributed in the water of bot compartments.[4] Sulphamerazine may perhaps distribu itself differently.

Necrosis, caused by occlusion of the blood supply muscle in the dog at open operation, has given similar result Aub and his colleagues[5] have shown that the plasma-lil fluid seeping from such injured muscle in 9 out of 32 animals caused a slowly developing and fatal shock when injected into other normal dogs. There was a close correlation between the clostridial counts of such fluids and their toxicity, which appeared to be chiefly due to exotoxin. Uninfected exudates were without significant physiological effect. Complete protection was conferred by injecting the recipient with antitoxin. In the rabbit, on the other hand, ischaemic necrosis of muscle by pressure without external injury[6] produces only "extravasation shock." The amount of plasma loss is proportional to the volume of tissue damaged. There is no infection and no delayed "toxic shock."

In man the response to muscle damage resembles that seen in the rabbit more closely than that in the dog; infection, when it occurs, is implanted from without rather than developed locally. Aub and his colleagues showed that no clostridia could be cultured from sixteen human muscle biopsies. Clinically, cases of muscle necrosis seen in this country without an external wound, as in the crush syndrome, have not been complicated by local infection, though such necrotic tissue would make an excellent medium for anaerobic bacteria. It seems probable, however, that if contamination through an external wound occurred growth would be rapid: it is in these circumstances that the findings of Prinzmetal and Aub and their associates in the dog can be applied. Prophylaxis by débridement and by administration of sulphonamide or penicillin is essential. This applies also, as is generally ecognized, to the more usual wounds involving muscle without prolonged pressure ischaemia, especially if there s any interference with blood supply. In this type of case, in which an external wound is associated with damage both to muscle and to vessels, the mortality is high, due occasionally to anuria, sometimes to infection, and sometimes to fat embolism from associated fractures. The experimental findings again emphasize the need for prophylactic treatment based on an early clinical assessment of the type and extent of damage sustained.

LEPROSY IN THE BRITISH EMPIRE

Sir Leonard Rogers has written a pamphlet entitled "The Foundation of the British Empire Leprosy Relief Association," a body which lately came of age,[7] but the pamphlet also epitomizes the history of the treatment of leprosy and urveys the extent of the problem in the British Empire. The author describes it as the "simple fact" that until thirty years ago the outlook for sufferers from leprosy was little better than in the times of Naaman the Syrian. The only measure up to then in common use was compulsory egregation, or, in plain language, imprisonment for life with no hope of recovery. The man who is chiefly responsible for an achievement should not also be its historian, or modesty will prevent him from giving an adequate ssessment of his own labours, but the work of Sir Leonard Rogers himself, briefly recounted in this publication, in obtaining the injection of the soluble sodium salts of the fatty acids of chaulmoogra and other oils intramuscularly, nd still better intravenously, is well recognized. As a result of this and other advances the problem of lowering the incidence of leprosy resolved itself into discovering and treating new infections in as early a stage as possible. The British Empire Leprosy Relief Association was founded in 1923. It must have been a daunting experience for those concerned, including Sir Leonard Rogers himself, to find Mansion House appeal, supported by a former Viceroy f India and two Secretaries of State, which aimed at a quarter of a million pounds, bring in only about one-sixtieth of the expected amount. But the officers of B.E.L.R.A. did not permit themselves to be discouraged, and gradually it acquired a workable income, and has managed not only to exist but to carry on enterprises surprising in their variety and range, of which a summary is given in this pamphlet.

The extent of the leprosy problem in the British Empire, when stated in figures, looks formidable enough. It is estimated that there are 1,200,000 lepers in India, 750,000 in the parts of Africa over which the British flag flies, and 50,000 elsewhere in the Empire. Fortunately, the problem is much simplified now that it is known that only from 200,000 to 400,000 of this total are nodular or lepromatous cases, requiring isolation. Sir Leonard Rogers discusses the essential points in the policy of B.E.L.R.A. for handling infective and non-infective cases, and the care of household contacts and of children born to lepers. On the need for further research he points out that a reliable curative drug for every type and stage of leprosy is still lacking, despite the intensive work of the last thirty years, and that care should be taken in speaking of the "cure" of such a disease at all, because even in the more amenable early stages relapses may occur. For this reason B.E.L.R.A. has put laboratory research and epidemiological studies and surveys in the forefront of its programme. Here the remarkable discoveries in the field of chemotherapy in recent years whereby a number of widespread and dangerous diseases have been combated hold out hopes of similar success against leprosy. In its twenty-one years B.E.L.R.A. has demonstrated that if given enough money it can greatly reduce, and perhaps at length eradicate, the most dreaded of all diseases.

BIRMINGHAM UNITED HOSPITAL

Birmingham United Hospital, which includes the General Hospital and the new Queen Elizabeth Hospital at Edgbaston, now has a ten-years history. Its latest annual report puts on record the work of a busy year. The General Hospital has been unable to bring all its beds into use, but its emergency in-patient work and its vast out-patient and casualty service have been fully maintained. The Queen Elizabeth Hospital has had 12,366 in-patients, of whom more than one-fourth, admitted from D-Day (June 6 of last year) until the end of 1944, were wounded men from the fighting Services. The ordinary peacetime capacity of the Queen Elizabeth Hospital is 576 beds, but the average daily bed occupation throughout the year was 648. The new hospital is now firmly established in its service not only to the city but to wide areas of the Midlands. A note is made in the report of the fact that one recommendation of the Goodenough Committee has been anticipated in Birmingham. The Vice-Chancellor of the University and the Dean of the Medical Faculty are members of the board of management of the United Hospital, and more formal arrangements for cross-representation have now been agreed in connexion with appointments to the staff both of the medical faculty and of the hospital. Another development, if present proposals go forward, is that the cancer service for the Midland area will largely centre around the United Hospital.

The Dissolution Honours announced on June 7 include a Viscounty for Lord Addison, M.D., F.R.C.S., Leader of the Labour Party in the House of Lords since 1940; and a Barony for the Right Hon. Sir Douglas Hacking, Bt., M.P., who has been a Crown nominee on the General Medical Council since 1932. Both awards are for political and public services.

BRIDGING THE GAP

REALISM AND HUMANISM IN MEDICAL TRAINING

BY

Ff. ROBERTS, M.D.

The most astonishing feature of the discussion raging on the medical curriculum is that the faults now so eloquently admitted are no new discoveries but have been well known for a considerable time. In 1932, to go back no further, the *Lancet* published a series of articles in which almost everything was said that is being said to-day. Deans of medical schools and others have uttered brave words which have been completely ineffective. Many of the medical members of the Goodenough Committee and of the witnesses whom they heard are those who, although occupying, or having occupied, influential positions, have failed to put their house in order. Two important groups of the profession the committee ignored: general practitioners, who are no mean judges of their training; and junior teachers, who are still young enough neither to have settled into an academic groove nor to have forgotten the difficulties which they experienced in their student days.

The Goodenough report must be judged not by the acclamation with which it has been greeted, particularly in the lay press, but by the answers which it gives to the following questions. Does it show a sufficiently fundamental insight into the problem? Does it take into account the inertia which is inherent in medical education? Has it succeeded in ascribing that inertia to human limitations, to the nature of medicine, to under-estimation of the difficulties of the problem, or to any other cause? Finally, do its proposals differ substantially from those which have been so frequently suggested, and have they any better prospect of attainment?

The chief problem is how to bring about a closer relationship, or, as the Goodenough Committee puts it, how to bridge the gap between the pre-clinical and clinical stages. Accepting this metaphor, we have to face the following facts. First, bridges already exist where the gap is narrowest. These are simple departures from the normal which can be adjusted physiologically, such as the treatment of myxoedema with thyroid extract. They, however, are exceptional; in general the gap is and must for long remain unbridgable, though of course it is slowly being narrowed. Secondly, wherever a reliable bridge is built there is no delay in using it. The vitamins furnish the best example. Thirdly, bridges have long existed without their being recognized until formally opened and strengthened for heavy traffic by the scientists: the East India Company gave their sailors fresh fruit 300 years before vitamins were discovered. Fourthly, it is fatally easy to build bridges strong enough to the outward eye but incapable of bearing the strain of practical use. Facts incontrovertible in the laboratory are applied to clinical medicine in a manner quite unwarranted. The best examples are the indiscriminate use of the hormones and the ready acceptance of the biased blurbs of research propagated by commercial travellers.

Fifthly, bridges are imagined where they do not exist. The problem is over-simplified by the popular tendency to present medicine merely as the study of disordered function. Disease, it is said, is dis-ease. But medicine is concerned with the infinite variety in relationship between three factors: the causative agency such as infection, malignancy, or degeneration; the reaction of the body to that agency; and the efforts of the body to continue its functions under adverse conditions. A picture of life being carried on in a bombed town is but part of the whole scene of desolation, and neither explains the cause of the catastrophe nor suggests the remedy. In some conditions, such as carcinoma of the oesophagus, the disorder of function is very simple. In others, such as appendicitis, it does not exist, because we do not know the function of the organ concerned. In others it is too obscure to be tracked down to any particular organ. Every radiologist knows how often cases are referred to him with a provisional diagnosis—"? stomach, colon, appendix, or gall-bladder." We may note also the wide difference in disorder of function shown by such closely allied conditions as intrinsic and extrinsic carcinoma of the larynx. Nor must we forget that preoccupation with disorder of function is the commonest cause of failure to discover the true nature of the disease. The best answer, however, to those who believe that disease is mainly disorder of function is provided by the existence of what we call functional disease—one of the best jokes that Nature plays on Man or Man plays on himself.

In demanding that medicine must be taught "as a smooth and logical development" of the pre-clinical subjects the Goodenough Committee has formed a conception of medicine which bears little resemblance to reality. It presents Hygeia as a pin-up girl flamboyantly overdressed in scientific finery, and it remains to be seen whether she proves more inspiring in this glamorous guise. If the medical schools transfer their worship to this new deity one of two things is bound to happen. The first is that the cleavage between physiology and medicine may be healed, but only to be replaced by a more disastrous cleavage between an artificial form of medicine and medicine as it really exists. The second and more probable result will be that the attempt will prove abortive, because the true nature of medicine will assert itself.

The Mixture as Before

The Goodenough report hashes up the old catchwords: less factual knowledge, ruthless pruning, better co-operation between pre-clinical and clinical teachers, and more attention to principles. Factual knowledge must of course be curtailed, but let us not fall into the error of minimizing its importance. There is nothing inherently wrong with factual knowledge provided that the items are related to one another. Every subject is in substance a mass of facts, and the student who, having a well-ordered mind, can memorize them must progress faster than the student not so endowed. As for "ruthless pruning," no metaphor could be more inept, as will be obvious to anyone who considers the original horticultural connotation of the term. If the sequence of thought is not to be utterly destroyed the necessary curtailment of the curriculum must be carried out not with ruthlessness but with the utmost circumspection. With the need for co-operation between pre-clinical and clinical teachers I have previously dealt. Here I need only repeat that the sole obstacle is the will to achieve it. Pre-clinical teachers have always had free access to the wards and to clinical material; they have failed to make use of these facilities because their own inclinations and interests lie in a different direction.

As for principles, we may well ask what these are and where they are to be found. The term "principle" is simple enough when applied to human conduct. In the physical world the facts of observation and experiment lead to the formulation of principles (more accurately termed laws) from which further facts can be predicted. The law of Avogadro, the periodic law, the phase rule, and Le Chatelier's principle form the basis of physical chemistry. But in the textbooks of physiology principles or laws are few and far between. There are, to give only a few instances, no laws concerning the functions of the spleen, cerebral localization, fat absorption, pituitary function. Physiology is concerned not with *principles* but with *facts* which have been obtained by experiment and observation and from which *functions* are deduced. Only in exceptional instances has knowledge of these functions been integrated into principles. And this applies with even greater force to topographical anatomy, which by its very nature is totally devoid of principles. How wide of the mark, then, is the Goodenough report when it says that "in the pre-clinical period students . . . are concerned primarily with the principles of the normal structure and functions of the human body."

Experience

We therefore see how superficial are the remedies proposed for bridging the gap. Our planners having failed us, let us turn to the educationists, starting from their main principle—a principle known to Aristotle and thus enunciated by Sir Richard Livingstone: "That almost any subject is studied with much more interest and intelligence by those who know something of its subject-matter than by those who do not; and, conversely that it is not profitable to study theory without some practical experience of the facts to which it relates."

How far is this principle applied in medical training? In the whole of physics and nearly the whole of chemistry every proposition can be proved by class experiment. The same is true of biology and anatomy in so far as these concern structure. This, however, is not to say that the presentation of these subjects is ideal. There must be something seriously wrong with the teaching of physics to make it possible for the Medical Research Council to publish a lengthy report (No. 161, 1931) based on the fantastic notion that a liquid expands when the tension to which it is subjected is removed. But the fact remains that these subjects are taught vividly by direct experience.

On the death, in 1907, of Sir Michael Foster, the first professor of physiology at Cambridge, his successor, Prof. J. N. Langley, wrote: "The primary idea of Foster's teaching was that scientific instruction should be based upon first-hand knowledge, and that a student must see and do things for himself in order to gain a real and lasting hold on any scientific subject."

How has the teaching of physiology lived up to this ideal? Some of the facts can be demonstrated on the human body, others in the test-tube and on lower animals, but by far the greater part of the subject is learnt indirectly from books. The whole of metabolism, absorption of food, blood formation, and the functions of the brain, semi-circular canals, cochlea, and reproductive organs are learnt in this way. Even the teachers have little, if any, first-hand knowledge of them, for they themselves have only learnt them from the books, with the result that the information when it reaches the student is second-, third-, or *n*th-hand. Let us take a typical example from a current textbook.

> "Suppose that a decerebrate cat be also deprived of its labyrinth. If the head be rotated about the long axis of the trunk so that the chin moves towards the left shoulder it will be found that the left fore limb extends and that the right fore limb suffers decreased extension. Experiment shows that it is the turning of the 'atlas' vertebra on the 'axis' which brings about this modification of postural tone . . . Suppose in another experiment that the neck be bent so that the right ear approaches the right shoulder. It will be found that the extensor tonus in both left front and left hind limbs is diminished. . . ."

This passage is by no means exceptional. There are pages and pages of the same kind of thing. It is all remote from experience, and the student has to make a mental image of it as best he can for examination purposes. It is true, of course, that many of these experiments cannot be demonstrated to a class, but what a splendid field this is for the cinematograph! Not only the cinematograph but even simple direct methods of demonstration are woefully neglected. Few students are shown the movements of the human stomach radiologically. doubt whether many pre-clinical teachers have seen them. This fascinating subject is too commonplace for them; they find it less trouble to teach it from the book descriptions of xperiments on the cat. The first principle of every teacher should be to present every part of his subject as realistically s possible.

The Value of Unexperienced Facts

But even if this were done there would remain a hard core of undemonstrable facts which would still have to be learnt indirectly. What is the intellectual value of subjects remote from experience? Let us turn again to Livingstone:

> "A schoolboy, who may know nothing of the realities which history or literature or politics or economics deal, can get this training from their study; their facts and theories are to him counters with which he learns to use his brain in these and related subjects; to argue a case and weigh evidence, to distinguish the relevant from the irrelevant, to seize the point at issue, to arrange his thoughts and marshal facts to support a theory, to discover when a statement is proved and when it is not, to reason logically and express himself clearly—in fact to play the great game of the intellect."

How do the pre-clinical subjects stand up to this test? As an example we may consider what the student learns about the cause of the bile-flow? In one book he reads, among other things, that "the contraction of the gall-bladder is brought about by the entrance of fatty foods into the duodenum. The contraction may be brought about by the hormone cholecystokinin, which passes via the blood stream from the duodenum to e gall-bladder." There the fact stands in all its hideous nakedness and gloomy isolation, without any other reference to cholecystokinin, a fact to be learnt and memorized. And there are hundreds of facts stated just as baldly. In another book the subject of pancreatic and biliary secretion is described with a wealth of detail. Among the causes of bile secretion, we are told, is the injection of secretin. After describing the other causes the author sums up by saying "that the expulsion of bile promotes pancreatic secretion by aiding the transference of secretin into the blood, and it augments the flow of the bile itself." If the student were not exhausted by the morass of facts through which he had floundered he might have sufficient freshness to reflect that here is a double vicious circle. For if the excretion of bile from the liver stimulates the formation of secretin, and if the formation of secretin in turn stimulates the excretion of more bile, why does the excretion of bile once begun ever stop? Similarly, if the excretion of bile stimulates the excretion of more bile why does the process ever stop? The student is bludgeoned into passive acceptance of orthodox teaching. Where is any scope to argue a case—to weigh evidence and to reason logically? The truth is that the pre-clinical subjects are very far from providing that training in "scientific thought and criticism" which, according to the Goodenough report, should be carried into clinical medicine.

As facts have accumulated with the years, their presentation has degenerated. Langley wrote of Foster's *Textbook of Physiology* (1876 edition): "The distinguished characters of the work are its good literary style, and its suggestive and impartial manner of discussing physiological questions. . . . A host of medical practitioners, who could not bring themselves to study *arid physiological facts* [italics mine] read it with equal pleasure and profit." Of how many modern textbooks could this be said? It is significant that Foster spent two years in general practice. Perhaps the experience so gained at least contributed to his warm human outlook. The true remedy lies not in the ruthless pruning of facts but in a fundamental reform in their presentation.

The Introduction to Clinical Medicine

The Goodenough Committee stresses the bewilderment which students feel on entering the wards, but it has entirely missed the important point that this bewilderment is felt in the measure that they have been led to expect "an easy transition" between the pre-clinical subjects and medicine. In the pre-clinical lectures they have been led to believe that a cerebral tumour must present a pretty physiological exercise in location, but they are soon disillusioned, for they find people talking in quite a different language, about headache, vomiting, and optic neuritis, and they may find reliance being placed on radiological rather than on physiological evidence. It comes as a rude shock to them to learn that the cases which present the classical pictures so dear to those with little experience are the few which have been carefully selected in the textbooks for the teaching of physiology, not for the teaching of medicine. Similar instances could be given from other branches of medicine. The student soon learns to discard his previous theoretical instruction, and who can blame him? In preferring the real to the unreal, the direct to the indirect, is he not obeying a sound human instinct?

Since structure is taught more directly and more vividly than function, the student enters the wards with a bias towards a structural and against a functional interpretation of phenomena, a bias which he retains throughout life. He fails to appreciate what is almost the first principle of medicine—namely, that wherever anatomical and physiological criteria are in conflict the physiological criterion should nearly always be accepted. On the advent of the radiological investigation of the digestive system failure to observe this principle sent the profession hurtling down an abyss of error from which it is only now painfully emerging. The number of patients who are told that they have "dropped stomachs" and who are provided with quite useless belts shows how much we have to learn about the wide variation in the size, shape, and position of organs which is compatible with normal function.

Yet even the teaching of structure fails. The student spends an immense amount of time in dissection, but his fingers are completely insensitive to the feel of the abdomen, muscles, joints, axillae, and groins. Nor is this failure rectified in the wards, for there he approaches the patient with a bias towards the abnormal. *Thanks to their training, there are many doctors who have a less intimate knowledge of the body than medical auxiliaries.* Masseuses often know better what they are feeling, and radiographers often know better from the clinical appearance of an injured arm whether the elbow, forearm, or wrist should be radiographed. The clinical acumen which these auxiliaries acquire is not surprising; it only shows how exuberant is the growth of curiosity when fertilized by opportunity and sheltered from the icy blast of pedagogy. I fear to pursue this line of thought lest it lead me to the conclusion that the whole of the student's curriculum can be debunked.

Intellectualism

We therefore see how fundamentally ill adapted, both culturally and vocationally, the pre-clinical course is for the training of doctors. The root-causes are three. First, promotion in the academic field is the reward of capacity for research rather than for the ability to teach ordinary minds. Research workers have so often said that students derive great benefit from contact with them that the plain man has not dared to question it. But while admitting that students should be taught by original minds we may very humbly question the doctrine that a man is a better teacher of things with which his students will come into daily contact *because* he is engaged in a research problem quite unrelated to their future work. Secondly, teachers are not taught how to teach. The Goodenough Committee recognizes this fact, but its remedy is singularly inept. The committee suggests the inspection of medical schools, but in a form foredoomed to failure so far as the quality of teaching is concerned, because the inspection is not to be carried out by a completely independent body. Thirdly, the evils of our methods of teaching and examination are such as automatically perpetuate themselves. The system to which students are subjected is the very system which produces the type of teacher by whom those students are taught. For by this system it is primarily the faculty for memorizing unexperienced facts which opens the doors to an academic career. Those who possess this faculty cannot put themselves in the place of those who are not so gifted, hence the neglect of the cinematograph and other simple means of demonstration. This too the Goodenough Committee has failed to understand. While it starts from the principle that the basic training should be the same for general practitioners and consultants, it abandons this excellent principle at the first opportunity, giving its warmest benediction to the establishment of an undergraduate school for "carefully selected students" who are to become "teachers, investigators, and consultants rather than general practitioners." Could any scheme be better devised for widening the gulf between the intellectuals and the rest of humanity?

The committee pays lip-service to the cause of humanism, but in reality comes down heavily on the side of intellectualism. It heartily endorses the self-satisfied words of one of its witnesses: "In the last limit [whatever that may mean] it is essential to place trust in those engaged in teaching and research." The tendency on the part of those whose interests lie mainly in research to enlarge and complicate their subjects regardless of their importance to students is apparently uncontrollable from within, and must therefore be controlled from without. It is precisely because no such control has been exercised that medical training has come to such a sorry pass. To the teacher-researcher the report promises an earthly paradise, but what does it do about the really simple things which affect the ordinary man? Are its proposals calculated to correct those faults which are so obvious to all who have eyes to see: the failure to arouse curiosity; the failure to teach observation and the memorizing of observations; the failure to teach students to marshal facts, to reason, and to use their common sense? The fundamental cause of the failure of the curriculum is the stranglehold by intellectualism on a subject which is essentially human and practical, a stranglehold which the Goodenough report is designed not to relieve but to intensify.

> Must be the mistress to this theoric."

Reports of Societies

URINARY COMPLICATIONS OF PREGNANCY

A joint meeting of the Sections of Urology and of Obstetrics and Gynaecology of the Royal Society of Medicine was held on May 24 for a discussion on urinary complications of pregnancy. Mr. F. McG. **Loughnane**, president of the Section of Urology, was in the chair.

Mr. **Joel Gabe** first described the changes which occurred in the urinary tract during pregnancy. As early as the third month there were changes in the upper urinary tract. The anatomical changes most often seen were dilatation of the calices, the pelvis, and the ureter as far down as the pelvic brim. The abdominal ureter was often elongated and might become tortuous, kinked, and laterally displaced. Kinking usually affected the upper third of the ureter and might be so marked as to obstruct ureteric catheters. Even before the uterus was large enough to exert pressure certain physiological changes occurred—namely, atony, relaxation, and stasis. These were generally regarded as due to the action of hormones elaborated by the placenta. If the urine of pregnant women were injected into virgin rabbits changes were produced in the urinary tract of the rabbits like those observed in the pregnant animal. It had also been shown that the amount of prolan B and oestrin excreted in the urine increased during pregnancy.

The stasis and atony which occurred were the perfect prerequisites for infection, and it was remarkable that this did not happen more often. Stasis was found in 73% of primiparae and 45% of multiparae. When excessive it might cause temporary renal impairment, but normally the total renal function was unaffected and there were no changes in the blood chemistry. After normal pregnancy retrogressive changes occurred in 60% of women within two weeks of delivery, and intravenous pyelograms were usually normal by the tenth day of the puerperium. Ureteral atony might persist for a fortnight or longer.

Calculus

After discussing some bladder complications Mr. Gabe spoke at length on urinary calculus, which was not, he said, strictly speaking, a complication of pregnancy, but rather a complication which occurred during pregnancy. If a woman was known to harbour a calculus she should be advised to have it removed before embarking on any future pregnancy. Calculus in the urinary tract was commonest at the ages between 30 and 50 whereas the majority of pregnancies were before 30. During pregnancy calculi in the kidney and ureter were found in about equal proportions and very rarely in the bladder. The symptoms in the early months were the typical ones of pain and haematuria, but after the fourth month a calculus was more likely to give rise to infection than to pain, and the kidney might be found enlarged from pyonephrosis. During the period of general atony calculi seldom passed spontaneously. Caliceal calculi were less harmful as a rule than those in the pelvis.

Generally the policy of waiting until after the termination o pregnancy was justified if there were no symptoms, if renal function was good, if infection was minimal, and if the stone because of its position, was unlikely to give rise to trouble otherwise the procedure to be adopted depended upon the stage of pregnancy and the site of the stone. Serious complications such as pyelonephritis, perinephric abscess, oliguria, anuria, an uraemia, required urgent treatment. An operation in the firs four months was much easier to carry out than later on, particularly upon the ureter, and there was a longer period fo the wound to heal soundly. For ureteral calculi cystoscopi methods of removal should, of course, be tried in all suitabl cases, and if the calculus could not be removed by this mean obstruction might be overcome by pushing it up into a mo dilated part. Advanced pregnancy was no absolute contraindication to operation if the patient's condition required i but, generally speaking, a conservative attitude should b adopted.

Tuberculosis of the Urinary Tract

Tuberculosis of the urinary tract complicating pregnanc was infrequent and usually presented itself as a sterile pyuri Although pregnancy was occasionally tolerated surprising well, most cases were made worse by it. The symptoms were exacerbated, the renal function deteriorated, and pyelographic films showed increasing destruction. The spread of tuberculosis during pregnancy might be due to lowered resistance and to increased demand for calcium, resulting in decalcification of nodules and liberation of tubercle bacilli. Usually severe bladder symptoms were present; frequency was marked both day and night. When tuberculosis developed on the top of pyelonephritis the change in the symptoms was marked and abrupt, and the organisms responsible for the pyelonephritis might disappear from the urine. Extensive lesions might develop in the course of a month. Early interruption of the pregnancy followed by nephrectomy gave the best results. Palliative treatment was indicated in cases affected by chronic urinary tuberculosis without untoward symptoms.

Mr. Gabe then briefly discussed neoplasms and solitary kidney, and in conclusion strongly advocated a full urological nvestigation in all cases with a previous history of urinary isease, and for all patients slow to recover from an attack of yelitis or who readily relapsed. If some of these complications, which were known to lead to chronic ill-health and even o-invalidism, were to be prevented, closer co-operation must obtain between the general practitioner, the obstetrician, and he urologist. As routine measures microscopical and bacteriological examination of the urine and an increasing use of intraenous pyelography were minimal requirements.

Pyelitis in Pregnancy

Miss GLADYS DODDS gave some observations on 287 cases of nte-natal pyelitis admitted to University College Hospital during e period 1927–44. The average age of the patients was 25.4 ears, and 185 were primiparae. The infection occurred most ommonly before the twenty-fifth week of pregnancy. The onset the majority of cases was sudden, with acute stabbing pain ferred to one or other side of the abdomen, often associated ith shivering, occasionally with frequency of micturition, and ss often with vomiting. The acute stage lasted on the average days, and thereafter the patient's general condition improved. a small number of cases—just over 10% in this series—the sease ran a more unfavourable course, the temperature remaining high, the general condition not improving, and anaemia ossibly developing as a result of the prolonged sepsis.

Of these 287 cases 2 patients died after the pregnancy had rminated—one a day after spontaneous premature labour the 29th week, and the other 9 days after hysterotomy at e 23rd week. On post-mortem examination one of them owed a mild degree of pyelonephritis and the other a pyelophritis with acute inflammation of the kidney, pelvis, and eters.

The early patients, 186 in number, were treated with large ses of alkalis, occasionally with acids and hexamine, and ly 4 so treated had sterile urine during the pregnancy. The cond group of 37 patients were treated by ketogenic diet or mandelic acid, and 5 of these had sterile urine after treatment. The third group of 64 patients were treated with sulphamides, and in 36 of these the urine became sterile during egnancy, the majority of them within one week of starting atment. Of these 64 patients, 7 were not readmitted to spital for subsequent delivery, and were therefore lost to servation. Of the remaining 57, 1 died, 3 had induced labour cause they did not respond to treatment, 1 aborted, and went into premature labour spontaneously during the first ute attack of pyelitis. Of the other 50 only 4 had recurnt acute attacks of pyelitis (a recurrence rate of 8%) during e pregnancy. Five had an acute recurrence of infection in early puerperium, and 3 of these, on investigation, were und to have hydro-ureter and hydronephrosis.

Out of the total number, 236 of the patients with ante-natal elitis were subsequently delivered in hospital of a viable etus. Signs of toxaemia developed in 73 cases before the d of pregnancy, and 2 patients had eclampsia. The incidence toxaemia was thus 30.9%, which was lower than that of the rmal clinic population. The incidence of toxaemia in 1,864 ent consecutive deliveries at University College Hospital s 36%.

Injury to Bladder during Childbirth

Prof. CHASSAR MOIR discussed the problems set by injuries the bladder resulting from parturition, and spoke in particular of two classes of cases—namely, patients with stress incontinence of urine and patients with leakage of urine from a vesicovaginal fistula. Stress incontinence, or incontinence on effort as it was sometimes called, was one of the commonest of gynaecological symptoms. It was the result of the stretching of the vaginal walls and supports which took place during childbirth. The usual treatment of cystocele by vaginal operation gave a very satisfactory result in the majority of cases, but it had to be admitted that stress incontinence was not invariably or necessarily permanently cured by such an operation, and a small number of women—perhaps 5%—reported back at varying dates with a return of stress incontinence, though the uterine prolapse or cystocele appeared to be completely cured. A possible explanation was that the shape of the lower part of the pelvis, formed by the symphysis and the lower pubic rami, varied considerably in different women. In some it might be impossible to brace the urethra and bladder neck well forward against the symphysis, and in such cases the functional result must remain unsatisfactory.

Prof. Moir discussed various methods which might be followed after failure with the simple plastic operation, and specially commended the Goebel-Stoeckell operation, with its recent modification (1944) by Aldridge, of New York.

> A ribbon of fascia from the muscles of the anterior abdominal wall is dissected up on both sides; the upper ends are free, but the lower ends are left attached to the pyramidalis muscles. A dissection is made through the vagina on both sides of the upper urethra and a passage made to meet the abdominal dissection above. The two fascial ribbons are now brought down and united below the urethra to form a supporting sling for that organ. Finally, the vaginal dissection is closed as for a simple colporrhaphy.

He had at first thought this to be an unnecessarily extensive and elaborate procedure, but he had since performed it himself in two resistant cases, with complete cure in one and a very satisfactory result in the other. The second patient he showed to the combined Sections.

Vesico-vaginal Fistulae

Prof. Moir then dealt with the subject of vesico-vaginal fistulae, once the most dreaded of childbed injuries. There were two forms of this injury after childbirth—one of them caused by operative trauma and the other by prolonged pressure of the foetal head. In the latter type there was necrosis of the bladder wall, but urine might not escape until after 8 or 10 days, when sloughing took place. He believed the vast majority of fistulae were curable by vaginal operation. He had read with disappointment certain recent publications in which the writers took such a gloomy view of the treatment of fistula that they advocated almost as a routine measure the immediate transplantation of the ureters. No doubt good results could be obtained from this operation, but the cost was high.

The essentials for success in the vaginal operation—which he firmly believed was applicable to almost every case of vesicovaginal fistula—were: (1) good exposure; (2) excision of scar tissue; (3) the use of inert and non-irritating suture material (not catgut, unless the infolding of a deep layer was obviously required); (4) drainage of bladder by a catheter connected to a Bunsen-bottle apparatus to ensure constant gentle suction; and (5) the keeping of the patient face down, or substantially face down, for the first 5 or 7 days after operation, the stitched area being then at a higher level than the rest of the bladder. Here Prof. Moir showed tables illustrating his own series of operations concerning 24 fistulae in 23 cases. In every case a closure was effected by the vaginal operation. All the fistula cases save three were cured by one operation. The three in which two operations had to be carried out were, respectively, a patient with seven previous operations, and another with eight previous operations, in each case with most extensive scarring of the vagina, and a patient who had suffered a massive sloughing of the cervix, vagina, and bladder after radium therapy for carcinoma of the stump of the cervix. Finally he quoted Schmitz:

> "One of the greatest causes of failure in fistula operation must be attributed to a lack of understanding of the problem involved on the part of the person who first failed to close the opening. The percentage of bad results mounts rapidly after each attempt at closure. The time to close the fistula is at the first sitting."

Correspondence

Blood Transfusion

Sir,—Dr. Rice Edwards (June 2, p. 780) justly points out that some of my statements on blood transfusion are open to criticism. Speaking as I was on the application of the lessons of war to civil practice I wished to avoid losing the outline of those lessons by digression into detail. I discussed transfusion in relation to the urgent resuscitation of the previously healthy man who has been wounded or injured. In this connexion the statement that "we know no limits in amount or rate of administration other than the needs of the patient" is correct; but to the second statement, that "fit men can take any amount of O (IV) blood," it might have been wiser to add "given by a skilled transfusion officer." The rapid administration of six pints of blood to a man not rapidly bleeding at the same time is not transfusion according to the needs of the patient, nor would a skilled transfusion officer have fallen into the error.

Walshe has told us that as facts accumulate the need for their synthesis and integration increases correspondingly. There is a danger that the mass of observations that have been published in relation to shock may cloud that native hue of resolution which should be the spirit of the resuscitation ward. We must endeavour to keep in touch with the mass of valuable research work that is in progress on "wound shock," but we must leave philosophic doubt behind when we come to the side of the pale listless man on the stretcher who has just been brought in from the battlefield or the factory. It is in the treatment of such cases that the broadcasting of memoranda intended for scientific eyes alone has been unfortunate. Dozens of kidneys are damaged beyond recovery by anoxia for every one that is blocked by corpuscles or myohaemoglobin. Hundreds of men die from blood given too late, too slowly, or in insufficient quantities for every one who suffers a reaction.

The resuscitation officer must find by observation and question if blood has been lost and approximately how much, and he must replace it rapidly and completely. He soon learns to assess his patient, to assess the blood in his bottles, to assess and treat reactions. During the Eighth Army's campaign in the Middle East some 100,000 bottles of blood were distributed by Lieut.-Col. Buttle and administered in the field by his officers. I believe I am right in saying that no fatal or even serious reaction was recorded in this service.

I am unrepentant in condemning the giving of blood during straightforward operations. Blood transfusion is not the way to combat shock that is not due to blood loss, and a smooth operation should lead to smooth convalescence without biochemical assistance.—I am, etc.,

London, N.W.8. W. H. Ogilvie.

Technique of Venepuncture

Sir,—Dr. J. W. Shackle must forgive us if we point out that all that his letter (May 26, p. 749) demonstrates is that if is possible for an expert clinical pathologist to take a needle out of a distended vein before releasing the tourniquet and not produce a haematoma. His technique is not the usual one, nor is it safe if the syringe is not sterile. His own statement that it is safe will not be admissible as evidence until he has followed up a large series of his venepunctures after an interval of six months, for the incidence of homologous serum jaundice is capricious and the incubation period is long enough for patients to be lost out of sight. What we were trying to determine in our paper (*Journal,* May 5, 1945, p. 625) was how the icterogenic virus could be passed from one patient to another via a communal syringe when the *usual* technique of venepuncture for withdrawal of blood is followed. Now the usual technique is undoubtedly to release the constriction *before* the needle is withdrawn, and we demonstrated that as a result of this manœuvre there is a reflux of blood into the vein. We have just gone to the trouble of examining every book on our bookshelf in which the technique of venepuncture is described and we find they are unanimous in their recommendations:

"If the tourniquet is not released before the needle is withdrawn, blood will pour out by the puncture wound and in a few seconds a haematoma will form." (Beck, *Laboratory Manual of Haematologic Technic,* 1938, p. 24.)

"*Before* withdrawing the needle, the constriction is released." (Harrison, *Chemical Methods in Clinical Medicine,* 1937, p. 305.)

"Remove the tourniquet *before* withdrawing the needle, otherwis extravasation will occur." (Hutchison and Hunter, *Clinical Methods* 1937, p. 587.)

"Release the tourniquet and then withdraw the needle." (Kolme and Boerner, *Approved Laboratory Technic,* 1938, p. 581.)

"Release the tourniquet and then withdraw the needle. If th tourniquet is not released before the needle is withdrawn, a haematoma will be produced." (Kracke, *Diseases of the Blood,* 1941 p. 598.)

"It is essential to remember to release the tourniquet befor taking out the needle, as failure to do this is the commonest caus of an unsightly bruise or haematoma." (Stewart and Dunlop *Clinical Chemistry in Practical Medicine,* 1937, p. 18.)

"When sufficient blood has been obtained, remove the tournique and then withdraw the needle, this order being necessary to avoi a haematoma." (Whitby and Britton, *Disorders of the Blood,* 1942 p. 511.)

"The needle should not be withdrawn until the tourniquet ha been released to prevent the formation of a haematoma." (Wintrobe *Clinical Haematology,* 1942, p. 200.)

The only variation is in the description of venepuncture fo special purposes, such as determination of haematocrit percentage or blood gases. In these cases we are advised to releas the tourniquet before even withdrawing the blood. Nevertheless, some blood must be allowed to enter the syringe to sho that the needle is in the vein, and therefore some reflux mus occur when the tourniquet is released:

"Est ist also unbedingt nötig, nach Einführung der Kanüle di Stauung . . . wieder aufzuheben." (Naegeli, *Blutkrankheiten un Blutdiagnostik,* 1923, p. 7.)

"If a tourniquet is used, it must be released as soon as the needl enters the vein." (Stitt, Clough, and Clough, *Practical Bacteriolog Haematology and Animal Parasitology,* 1938, p. 291.)

In our paper we indicated that reflux might be avoided b inserting the needle upstream into the vein. Dr. Shackl suggests that it can also be avoided by removing the needl before releasing the tourniquet. We condemned subterfuges o this kind, because reflux due to negative dynamic pressure not the only way in which infection may be transmitted whe an unsterile syringe is used for venepuncture. In particula it has to be remembered that the cross-sectional area of th piston of a 10-c.cm. syringe is nearly 1,000 times greater tha that of the needle and that therefore an accidental displaceme of the piston of no more than 1/20 mm. is sufficient to forc liquid from the syringe back into the vein. A slip of th piston of this amount, which is imperceptible even to a stea hand, may easily occur when the piston is released after withdrawal. Also, it is not usual to dry the communal syrin after rinsing between cases and therefore the interior contai a little fluid. Dr. Shackle is aware of one consequence of th in his insistence on a tight piston. Unless it is tight, the pist may slip down the barrel after the sterile needle has be fitted, and if it is pushed home again some of the moisture the syringe will be forced up to the tip of the needle. D Shackle may avoid this hazard with his tight piston, b suppose he stabs the patient, withdraws the piston, and blood comes. Even worse, suppose only a little blood com and he realizes he has transfixed the vein. One can't belie these things never happen to Dr. Shackle, even after 50,0 venepunctures. Now what happens? We are afraid he w stop trying to withdraw his piston and it will be sucked ba and drive a little of the contents of the syringe on to the of the needle.

The final question is whether Dr. Shackle would take syringe with which he had just aspirated a streptococ empyema and use it for venepuncture in this way. We ce tainly shouldn't. We have now learned that blood fro apparently healthy men and women may contain an icteroge virus and we must regard any syringe which has been us for venepuncture as possibly infected. To an increasing ext nowadays venepunctures are being performed by orderli technical assistants, and graduates with non-medical qualifi tions, who are not expert pathologists and who have not h the discipline in asepsis which doctors and nurses sho acquire by working in surgical wards and in surgical theatr This trend is inevitable if medical man-power is to be used the best advantage. We believe that these people must be taught methods with a maximum safety factor; in other words, they must use completely sterile apparatus.

At this stage of the war it is admittedly hard to obtain and store large quantities of sterile apparatus, but the difficulty can be overcome. The Record syringe is tricky to clean and it does not stand frequent sterilization by heat; it is not an instrument for routine use. All-glass syringes are to be preferred as they are easily sterilized, complete with needle, by dry heat or by autoclaving; they also stand boiling well. Where very large numbers of specimens have to be taken, the difficulty can be met by using either a needle alone or blood-collecting tubes as figured by Stitt, Clough, and Clough (*loc. cit.*, p. 881, Fig. 28). Dr. Shackle will remember these tubes were in routine use at Guy's Hospital over fifteen years ago. In the future one hopes that the pathological services will supply sterile evacuated venules of the Behring type, which could be recovered and used again, as now happens with the M.R.C. transfusion kits. In any event, we believe that we must take the risks of venepuncture rather more seriously than Dr. Shackle if we are to make pathological investigations safe for the patient and protect ourselves from unjustifiable criticism.—We are, etc.,

Radcliffe Infirmary, Oxford.

Masking Syphilis with Penicillin

Sir,—The following may be of interest.

A soldier exposed himself to venereal infection in North-West Europe on Oct. 10, 1944. He developed a discharge on Oct. 14; gonococci were demonstrated, and 20 grammes of sulphathiazole were given in four days; the discharge ceased, but returned after three days and gonococci were present again. On Oct. 23 100,000 units of penicillin were administered in five injections of 20,000 each at three-hourly intervals. The discharge cleared rapidly, but on Dec. 13, 1944, a small ulcer appeared on the glans penis with a mild balanitis. On Dec. 13, 14, and 15 dark-ground examinations were negative and the Kahn reaction was negative on the first of these days; simple washes were applied and the sore healed in seven days. On Dec. 31 three small ulcers appeared on the margin of the prepuce and *Sp. pallida* were present; the Kahn reaction was negative: 2,400,000 units of penicillin were given over a period of 7½ days, and on Jan. 8, 1945, the sores were healed. The incubation period was therefore approximately 64 days, reckoning from Oct. 10 to Dec. 13, 1944, or 82 days reckoning from Oct. 10 to Dec. 31.

This case illustrates well the effect of a comparatively small amount of penicillin in delaying the appearance of a syphilitic sore, and suggests that every case of gonorrhoea treated with penicillin should be kept under careful observation for syphilis; we do not yet know for how long this should be, but probably three months as a minimum, and it may be that a period of six months, which is routine in the Army, is safer.—I am, etc.,

T. E. Osmond,
Brigadier; Consulting Venereologist to the Army.

London, S.W.1.

Diarrhoea in Chronic Malnutrition

Sir,—Non-infective diarrhoea associated with diminished food tolerance and generalized malnutrition is fairly common in my experience among the aged sick admitted to this hospital. These cases present features analogous in many respects to those seen in returned prisoners of war who suffer from malnutrition and dietetic diarrhoea. In combination with a controlled food intake (vitamin and mineral supplements where indicated) I have found crude liver extract to be a useful adjunct in the treatment of these cases. Four c.cm. daily is given parenterally into anaesthetized areas for a period of one week, and then on alternate days for a further week. I have found dietary restrictions unnecessary in most cases after this period. Relapse is uncommon if tolerance to a well-balanced diet is achieved. However, in those cases where clinical evidence of a vitamin-B-complex deficiency is pronounced at the outset weekly injections are continued for longer periods.

My sole case of a returned prisoner of war who showed chronic malnutrition and a non-infective diarrhoea did well with this treatment. He was free of diarrhoea by the third day and on the seventh day was demanding, successfully, a normal diet. Hypoproteinaemia, anaemia, and pitting oedema of the extremities were present in this case. In addition, there was activity in a right lower lobe bronchiectasis.

In view of the topical importance of this subject I would suggest that controlled observations might be made on the value of this therapy (if such has not already been done), particularly at centres where a sufficient number of cases present themselves.—I am, etc.,

P. Harvey,
Senior Resident Physician.

St. Stephen's Hospital, S.W.10.

Carbachol and its Antidote

Sir,—To Prof. J. H. Burn's letter (June 2, p. 781) I reply with diffidence. Any statement from so eminent a pharmacologist must command respect. I venture to submit two criticisms.

First, the undergraduates and carnivora of Oxford, who have all survived their carbachol experiences, are not patients handicapped by disease and operation. Secondly, Prof. Burn admits that if atropine injection is delayed until "carbachol has brought the patient to the point of death" all is not well. But is not such a delay inevitable, since house-surgeons have numerous duties? To the true pharmacological latent period of the action of atropine must be added other valuable moments—the resident must be found, he must decide whether the collapse is serious or not, he must find a vein.

Prof. Burn's criticism of my use of "often" in relation to hypertension observed in patients who have received 100 mg. of carbachol is quite fair. It was a *lapsus calami*. In the trial of the "moryl" case, in addition to the clinical records of the deceased, those of two patients who survived a dose of that magnitude were in evidence. These cases all showed gross hypertension, although atropine had not been given. I imagined that the nicotinic actions on ganglia and adrenals had been greater than the muscarinic effects. I was not certain that ventricular fibrillation could be excluded as a cause of death in the fatal case. Indeed I must dissent on a third point. I have more than once seen adrenaline produce ventricular fibrillation in cats untainted by chloroform.

I am also under the impression that the work of Starr and his colleagues showed that the action of atropine against carbachol symptoms was slower and less certain than that against other choline esters. *Tot homines, quot sententiae.* Atropine should doubtless be given as antidote for collapse due to a therapeutic dose of carbachol. I am not satisfied that the pressor action which seems to have obtained in the cases mentioned above would have benefited by injection of atropine. In the case of collapse due to a small dose of carbachol I should prefer as antidote a parasympatholytic agent devoid of central effect on the cardio-inhibitory centre.

There is perhaps a need for a fresh inquiry, based on clinical data, into the safety of carbachol used as a pharmacological catheter.—I am, etc.,

Hugh Dunlop.

London, W.1.

Treatment of Impetigo

Sir,—A former teacher of mine used to say that if you were prepared to be sufficiently meticulous in the dressing of the lesions of impetigo it did not really much matter what medicament you used upon them; they would eventually get well. The authors of the article on impetigo (May 19, p. 699) seem to have come to much the same conclusion. It is certainly to their credit that they appear to be willing to spend twice daily upon each of their patients about the same length of time as they must have spent in the writing of the article; but in case some of your readers conclude that there has been no advance in the treatment of the disease in the last thirty years, I feel the following remarks are justified.

First, the authors have written *Faust* without Mephistopheles, for although they do not mention it, the prime "villain of the piece" in impetigo is not the poor sulphonamides but a coagulase-positive *Staphylococcus aureus*, and one has no right to dismiss antiseptics and "sulphonamides" without taking this into account. It is as illogical to employ sulphanilamide for impetigo as it would be to use streptococcal antiserum for a man with boils. In an army over-seas, jealous of its man-power for battle, one has sought to achieve a "time to cure" not of 10.4 days, still less of 22, but rather of 5 or 6 and, recently especially, one has begun to succeed. From experience gained there I think it safe to conclude that in the post-war world only two drugs will be considered—namely, penicillin and sulphathiazole. Two methods of using them are as follows:

1. *Penicillin.*—Use freshly prepared solution, 200 units per c.cm. Shave the parts, remove crusts, then spray with the solution, allow to dry, and leave exposed. Repeat the spraying twice daily for 4 or 5 days.

2. *Sulphathiazole.*—Use as a 15% lanette wax cream. Shave and remove crusts, then apply the cream; and cover with lint and secure with bandage or strapping. Leave untouched for 4 days. If not wholly cured then, remove the crusts once more from the unhealed parts, re-apply cream and dressing, and leave 2 days more only. Do not use the cream further on that patient.

The penicillin is probably slightly the more effective and for the patient is certainly the more pleasant. But the rapid deterioration of penicillin at room temperature is a serious drawback. Far-seeing dispensing chemists should now be buying refrigerators and will presently, I dare say, be delivering a penicillin spray to the doctor, twice daily, at surgery hours.—I am, etc.,

B.L.A. H. A. DEWAR,
Major, R.A.M.C.

Therapeutic Use of Quinine

SIR,—I have been repeatedly informed that there is at present a restriction on the therapeutic use of quinine, other than for the treatment of malaria. I would appreciate any reliable information about the legal position, and would like to suggest that the law (if any) restricting its use should be perpetuated in regard to the use of quinine as a means of reinforcing a medical induction. In my capacity of obstetric consultant I have encountered three cases in six months where intra-uterine death of the foetus occurred following the use of quinine for induction. There was no obvious reason for carrying out the induction, and there was no other apparent reason for the death of the foetus. Stillbirth is still one of the major tragedies of midwifery, and even an infrequent cause should be completely eradicated. Quinine should be reserved for the extinction of the anopheles, and not applied indiscriminately to the human race.—I am, etc.,

Cambridge. OSWALD LLOYD.

*** By an Order made by the Ministry of Supply (S.R.O. 1942/2668), quinine and allied drugs, both natural and synthetic, may be used only for the control of malaria. The one exception is that quinidine may be used for treating cardiac arrhythmia. The restriction, however, was imposed to conserve quinine, not intra-uterine life, and will doubtless be removed when the supply of quinine again becomes adequate. Its effect on the parturient patient and foetus does not concern the Ministry of Supply, and legislation of the kind suggested by Dr. Lloyd would have to be part of an Act of Parliament.—ED., *B.M.J.*

Rheumatism and Orthopaedics

SIR,—I had the privilege of hearing Sir Adolphe Abrahams deliver the inaugural lecture at the postgraduate course on rheumatic diseases, organized by the Rheumatic Unit at St. Stephen's Hospital, L.C.C., in March this year—an address which subsequently appeared in the *Journal* of May 12 (p. 671). Sir Adolphe reviewed comprehensively the whole subject and emphasized particularly the pitfalls in the diagnosis of "rheumatism," suggesting that this, together with differential diagnosis and treatment, should be primarily the domain of the general physician.

I have for long emphasized to students of the rheumatic diseases that, e.g., rheumatoid arthritis is not exclusively a disease of joints, but is, in fact, a general systemic disease with secondary manifestations in the joints, just in the same way that pulmonary tuberculosis is acknowledged to be not purely a disease of the lungs but actually a general systemic disease with secondary manifestations in the lung. Both these diseases necessitate a full knowledge of general medicine, for they may at one time or another simulate almost any disease in general medicine (*Postgrad. med. J.*, January, 1944). It follows, therefore, that they are or should be primarily the concern of the general physician rather than of the ultra-specialist if successful results are to be achieved. The ultra-specialist may not look beyond his own more limited province, which has meant, in the case of rheumatoid disease, that the local joint manifestations may have been treated without relation to the general background of the patient. It is my firm conviction that the rheumatic diseases must resume their rightful place within the province of the general physician if any success in their radical control is to be achieved; for successful results are obtainable if the disease is diagnosed in its early manifestations, and if adequate facilities for treatment over a prolonged period of time are readily available. For these reasons such terms as "rheumatologist," "phthisiologist," are anachronisms which should be abolished. On the other hand, there is a purely medical side to orthopaedic work which is concerned with the prevention, as opposed to the treatment, of deformity which comes within the domain of the general physician specially interested in the rheumatic diseases.

A scheme to ameliorate the position and to control the rheumatic diseases should, in my view, be planned on a regional basis, with adequate in-patient accommodation and diagnostic facilities for long-term treatment on sanatorium lines, in specialized units within the framework of a general hospital rather than in a specialized hospital. Such a system offers the outstanding advantage of facilities for collaboration between the physician and his expert colleagues, such as the orthopaedic surgeon, the physical medicine specialist, the pathologist, the biochemist, surgeons of specialized departments, the psychiatrist, the masseuse, the social worker, the dietitian, the occupational therapist, etc.

No one wishes to belittle the invaluable restorative work of the orthopaedic surgeon—an important member of the team—in the sphere of the rheumatic diseases, but the underlying principle should hold good, that in the interests of the control of this widespread scourge the rheumatic diseases must return to their rightful place within the province of general medicine. —I am, etc.,

London, W.1. PHILIP ELLMAN.

Artificial Respiration

SIR,—It is with some trepidation that I enter this correspondence as my experience of artificial respiration consists of three cases of drowning, although I have had plenty of experience of it in anaesthetic practice. It was while trying to resuscitate one of these cases that I found a method of artificial respiration which I think is superior to any of the usual methods. This case was in a child. When I started Schäfer's method I could get no result and I found his mouth and pharynx full of vomitus. This was cleared away, but on restarting Schäfer's method more of the stomach contents were regurgitated and very little air could be either expressed or inspired. I picked up the child, put a leg over each shoulder with the trunk hanging down in front of me, facing me. I then began pressing the thorax against my own body and immediately a stream of water and vomitus issued from the child's nose and mouth. Subsequently air could be heard going to and fro into the lungs in greater quantity than before, and with very little effort on my part. The child's lips, ears, and cheeks became pink, showing circulation and oxygenation to be good, but I was unable to revive him.

The advantages of this method are:

1. Owing to the head hanging vertically downwards the tongue, which in Silvester's and Eve's methods falls back and obstructs the airway, tends to come away from the posterior pharyngeal wall and so frees the airway.
2. The hanging-down position allows free drainage of the lungs, mouth, and pharynx of inhaled material and vomitus.
3. The position ensures filling of the right side of the heart and so facilitates the pumping action of the thorax on the circulation and increases the cerebral blood pressure.
4. As the arms are hanging down there is a considerable pull on the pectoralis muscles, which helps the elastic recoil of the chest on inspiration as in the Silvester method.

5. As the body is in close contact with the rescuer's body, some heat is derived, which is of great importance in helping revival (Eve, *Brit. med. J.*, 1943, **1**, 535).

6. Furthermore, in this method the rescuer can, if he is strong enough, walk with patient to a place of safety or to where resuscitative apparatus is available (e.g., in a factory) while continuing the artificial respiration.

7. The thorax with this method is not compressed by the weight of the body as it is in Schäfer's method.

8. If difficulty is experienced with the airway, artificial respiration may be carried out with one hand while the tongue and jaw are held forward with the other.

9. No apparatus is required.

In some cases it would be easier to hang both legs over one shoulder, or if necessary the rescuer can be sitting and some of the weight taken by the patient's feet. The main disadvantage is that the method cannot be used with an obese patient.—I am, etc.,

Glasgow. ANDREW TINDAL, M.B., D.A.

Congenital Defects and Rubella

SIR,—I have read the annotation on congenital defects and rubella (May 5, p. 635) and think that the investigation which I am making at the Infants' Hospital, London, in connexion with rubella during pregnancy producing deafness in the child may be of interest.

Questionaries have been sent to past and present patients of my own, and to addresses kindly provided by the principals of various deaf schools. Those sent to parents of children over 5 years of age have brought in little information, chiefly, I think, on account of the fact that after a lapse of years the mother's recollection of happenings during pregnancy is not clear, and also the varied and sometimes slight symptoms of rubella. I am therefore confining myself to children born after the 1939–40 epidemic of rubella, and figures are very significant.

Deaf children born in 1940–1: Boys 55, girls 30—total 85.

History of rubella during first 4 months of pregnancy: Boys 11, girls 13—total 24.

Some of these children also have defects of the eyes, and at least three have defects of the eyes and heart. In all these 24 cases rubella was diagnosed, and there are at least six more where it seems extremely probable that the mother suffered from it without it being recognized. Of the remaining 61 cases, in 7 the deafness is hereditary, and in 13 was caused by meningitis. Of the 41 unaccounted for, 11 had measles and 3 whooping-cough during the first three years of life.

It may also be of interest—as this is a point on which so far have not found any literature—that out of 85 deaf children, 3 are left-handed or ambidextrous, 16 of these having left-handedness in the family; 11 are right-handed, but have left-handedness in the family. The percentage of left-handedness in deaf children is even higher in the wider range of ages.—am, etc.,

SYLVIAN M. MARTIN, L.C.S.T.,
Speech Therapist, Deaf Mute Clinics,
Infants Hospital, and Metropolitan Ear, Nose and Throat Hospital, London.

Intravenous Arsenic in Anginous Glandular Fever

SIR,—I have been much interested in the article by Lieut.-Col. Shirley Smith and Major Trevor Shaw (April 28, p. 581). Their observations on the beneficial effect of intravenous rsenic injections in cases of anginous forms of glandular fever re an important confirmation of the therapeutic results obtained in this disease by Friedemann and Elkeles (*Dtsch. med. Wschr.*, 931, **26**, 1). Three patients were treated with 0.15 g. neosalvarsan intravenously; 24 hours after the injection the emperature dropped to normal and a striking improvement of the severe throat lesions and of the general condition occurred. Two patients were treated by repeated painting of their tonsils with neosalvarsan 0.3 g. in 10 c.cm. of glycerin. In these cases similar good results were obtained within 48 hours.

In 9 out of 17 cases of anginous glandular fever large umbers of Vincent's organisms were found in the throat lesions. In some of these cases no Vincent's organisms were detected from swabs taken from the surface of the tonsillar membranes, and only on removing the membranes by dissecting forceps could the spirochaetes and fusiform bacilli be found. The frequent finding of Vincent's organisms, the successful treatment with arsenic, and the increase of mononuclear cells in the blood are features also met with in Vincent's angina. Although the clinical picture and the Paul-Bunnell test should assist in differentiating glandular fever from Vincent's angina and other throat lesions, it seems likely that aetiologically some of the anginous forms of glandular fever are only more severe and generalized reactions to Vincent's angina.—I am, etc.,

London, W.1. A. ELKELES.

Oxaluria in Tropical Climates

SIR,—In the *Journal* of April 28 (p. 590) there is an article by Col. J. M. Black on oxaluria in British troops in India. Of 77 cases admitted for urological conditions, oxaluria was a feature in 43 (55%), being associated with renal colic in 20, with haematuria in 15, and with epididymitis and cystitis in 8 cases. Col. Black considers that diet (tomatoes and strong tea) plus inadequate fluid intake cause oxaluria; haematuria binds the crystals of oxalate together with fibrin and a calculus results. He surmises that excessive formation of vitamin D by sunlight may be another factor favouring tropical lithiasis.

The subject of tropical lithiasis is very interesting; the condition is widespread, and has been studied extensively in South Africa, Mesopotamia, and America, as well as in India (by Sir Robert McCarrison). Conditions favouring stone formation in the urinary tract are: (1) an alkaline ash diet, high in calcium; (2) dehydration of the body; (3) avitaminosis A; (4) any infection of the urinary tract.

Oxaluria is very common in tropical countries and is harmless if certain rules are observed. They are: drink plenty of plain water that is not too "hard" ("plenty" means three gallons a day per man in hot weather); take adequate vitamin A in the diet; avoid infections of the urinary tract; take adequate vitamin C (the haemorrhages in eight of Col. Black's cases were probably due to "inapparent" scurvy). The excessive formation of vitamin D by sunlight is not, I think, a factor in the formation of urinary stones unless the "rules" are badly infringed. Among the "infections" of the urinary tract to avoid should be included schistosomiasis.—I am, etc.,

Portsmouth. FRANK MARSH.

Starvation in India

SIR,—It is sad to think that the findings of the Bhore Committee investigating the cause of so much ill-health in India are already being discounted, the reason being that India cannot afford to put matters into such a condition as is necessarily precedent to making the people into a healthy and prosperous nation.

The report of the recent Bengal Famine Inquiry Committee has revealed a shocking state of things. Over a million-and-a-half Indian people have been starved to death, due in part to neglect by both Central and the Provincial Governments. Such a wholesale "slaughter of the innocents" is a horrible disgrace, and unless some strong measures are taken by this country the near future of India is very black. We have been told of how the starved inhabitants of Greece were reduced to such a state of weakness that they lent themselves to be tools of any clamorous leader, so that with difficulty the risings were put down. In a sub-continent like India, where perennial starvation has reduced the people to a low level, the conditions are being prepared for the next world war. A look at the map of the eastern hemisphere shows that India is the centre of the British Commonwealth, being equidistant from Great Britain, South Africa, and Australia, and if we hesitate to do the right thing by the Indian people now at once, however expensive it may be, the English language alone will be all that is left to us.

The children of India need milk. Milk has been of striking benefit to the school-children of this country as well as to pregnant mothers. If milk is necessary for the people of Great Britain it is equally important for milk to be distributed to the people of India. We talk of the illiteracy of European countries, but it is not to be compared with that of our fellow citizens in India. It is only something of which we ought to be ashamed. Mothercraft classes such as I pioneered also have been of great value to this country, as evidenced by the presence of so large a number of young happy mothers with healthy contented children. Are Indian babies and mothers to be placed on the same footing? Are quarrels between British and Indian politicians and governments to continue to the disgrace of both?

If we, as a profession, both individually and collectively, bring pressure to bear on the Government, which seem to be unable to realize the seriousness of the situation or to know what they ought to do, they may be made to realize their responsibility before it is too late.—I am, etc.,

Swansea. G. ARBOUR STEPHENS.

Shall We Nationalize Medicine?

SIR,—I have just read Lord Horder's article "Shall We Nationalize Medicine?" (March 17, p. 357). Lord Horder attempts to detach himself from "this business of right and left," but succeeds in presenting only a case against State medicine. Without finally assessing which system is likely to provide the better all-round service, I feel that it is only fair to point out some of the weaknesses of Lord Horder's argument, and to say something of the other side.

Does he, for instance, imagine that the happy doctor–patient relationship, the importance of which he rightly stresses, flourishes to the same degree in the crowded out-patient department as in the private consulting-room? In the Army we have learnt much of the defects as well as of the advantages of what is really a State medical service functioning under abnormally difficult conditions. Our conclusions will differ according to our experiences, but I would say that one thing which does not seriously suffer is the doctor–patient relationship, except, of course, by military necessity, as when casualties have to be evacuated from forward to base areas, and continuity of treatment is interrupted in consequence. Indeed in many respects the doctor–patient relationship is far more honest and beyond reproach than in civil practice. Psychological patients are not put off with a bottle of medicine, and the "constant attender" or "near-malingerer" is promptly told the truth.

Moreover, paradoxical though it may sound, the Service doctor wields far more power than his colleague at home. No commanding officer could survive a medical report which said that the morale of his men was poor, that psychological illness was in consequence prevalent, that the barracks were dirty, and the standard of nutrition low. Yet every panel doctor knows that these are the causes which bring the majority of his patients to the surgery, and in Signals phraseology, he can do nothing, repeat nothing, about it.

Let us admit that in the preservation of our liberties we have fostered a system which shuts its eyes to most of the main causes of illness. Let us remember that psychogenic ailments are the commonest of all, and that our system has done little or nothing to prevent or to cure them but much to encourage them. Let us realize that though the privileged few can practise for their privileged patients a system of medicine probably freer from hypocrisy than that of any other country, the majority are still doomed to dispense bottles of medicine in overcrowded surgeries to patients whose real problems they have never had time to consider or investigate. Let us try to preserve as much as possible of the values of the voluntary hospital, but do not let us forget the disgrace of their waiting-lists. Let us in fact realize that as a profession we have failed in many respects, and in that spirit of modesty try to reconstruct boldly, preserving our liberties only if they do not conflict with the good of the service as a whole.—I am, etc.,

India. ROBERT PLATT.

The Integration of Medicine

SIR,—How delightful to read such a discourse as appears in the opening pages of the *Journal* of May 26! As a reminder of the method as well as the substance of an address we could wish for nothing better. Dr. Walshe's dissertation on the integration of medicine is a timely statement of some of the problems constantly present in the minds of those who have a real interest in the future organization of medical teaching, and more especially in regard to the extending system of whole-time teachers in the various departments of a medical school. The integrative forces are unlimited in their scope and value for the teachers and the students, if only to maintain in constant focus the interrelationships of apparently diverse phenomena and facts. In regard to the students, the earlier that the idea can be inculcated the better. The art of diagnosis lies largely in the integrative process, bearing in mind that clinical experience is a dominant factor. With this in mind, therefore, it would follow that the clinical method, when properly and fully integrated with the ever-widening scene of collateral observational or experimental data, is the medium in which a medical school should live.

Persons holding key positions in a teaching centre cannot afford to overlook Dr. Walshe's wise words, more especially the following: "Thus it happens that those responsible for the training of our successors too often find themselves imparting unrelated categories of information and partial and often conflicting generalizations culled from different fields of medicine, and it is becoming nobody's business and seems less and less within anyone's capacity to teach medicine as a whole, or to build into a coherent body of knowledge the several contributions of the specialists." In short, Dr. Walshe's address should be read and re-read until the ideas therein permeate the mind and leave a "proportional representation" in the general build-up of our future medical teaching.—I am, etc.,

Birmingham. A. V. NEALE.

SIR,—Dr. F. M. R. Walshe's oration on the integration of medicine (May 26, p. 723), which is full of wisdom, suggests to me—and I am sure to many others—that a course of lectures on medical practice by senior general practitioners of wide experience should be made *compulsory* in all medical schools. Then only will we get a proper appraisement of the clinical methods and elaborate techniques with which students are forced to acquaint themselves to satisfy the examiners. They should be delivered to all students in their final year, or, better still (since the curriculum is already overloaded), now that independent practice is not permitted (or at least discouraged), when a postgraduate appointment is being held in an accredited hospital they might be delivered during those fruitful months. Without these essays in practical experience by men who know, the young doctor suffers bewilderment and frustration when he first goes out into the world to stand on his own feet.—I am, etc.,

C. H. REINHOLD,
Winchfield, Hants. Colonel, I.M.S. (ret.).

Medical Missions

SIR,—I have just returned from India after 22 years as a medical missionary, and my *Journal* for March 3 forwarded thence has only just reached me. I was, of course, delighted to see the annotation about medical missions (p. 303), but I should like to correct the impression that is inevitable if one reads the quotation near the end of the article: "Dirty, lonely, unpleasant, uncomfortable service, the mission hospital stands for that." No doubt there are some mission hospitals which "stand for that"; but I have been operating daily for over 20 years in a theatre where just as much trouble is taken about asepsis as in a London hospital, and I know dozens of medical missionaries in India who have been doing similar work. There is no excuse for a medical mission hospital being "dirty." Certainly, when a cholera epidemic is on, and one has to go about in small farmhouses or even hovels, one is up against dirt. But even in these places entirely sterile intravenous infusions can be given, and are usually the best means of saving life.

As for being lonely, that is a matter of circumstance, and in many mission hospitals there are far too many patients and far too much work to allow of loneliness, and several or many colleagues, both European and national. Unpleasant? No, a thousand times no. Service of one's fellow men in the name of Christ may be arduous, but is never unpleasant. As a medical missionary for over 20 years, may I say that I have never ceased to be thankful that in 1922 I decided to take up this work. But may I emphasize, too, that he who would be a medical missionary, besides being sure of his "vocation," should also be a well-trained man (or woman), with two or three years of postgraduate experience, and should also be pre pared for responsibility, if it is thrust upon him, and equally ready to take a humble position as a junior colleague of Chinese, Indian, or African, if circumstances so direct. The mission field has no use for second-rate men or women.—I am, etc.,

Cambridge. T. Howard Somervell, F.R.C.S.

Housing the Returned Consultant

Sir,—Major H. B. Stallard (June 2, p. 787) correctly draws attention to some of the present difficulties in London for housing the consultant. This state of affairs has engaged my attention since the early part of the present year, and official figures I have obtained from a reliable source disclosed the facts that in the area between Oxford Street and Marylebone Road the Army have requisitioned at least 3 houses (one empty for the past two months), the Air Force 8 houses, and the Ministry of Works no fewer than 45 houses. In the House of Commons on May 10 Sir Ernest Graham-Little, on a question to the Minister of War, received the reply: "I regret that I am at present unable to release any of these houses." To a further question asked by Sir Ernest on May 31 Mr. Churchill replied: "The majority of the houses in the Harley Street area requisitioned by Government Departments are used to house American officers, so as to reduce the pressure upon the limited hotel accommodation of London; as offices for French Missions and branches of the French Embassy; and as hostels. The possibility of reducing the number retained is being examined with the occupying authorities and any houses which can be vacated will be released. Five requisitioned houses now vacant are being released immediately."

The present difficulties are, however, further complicated by the sale of property in this area, and tenants who might have considered themselves reasonably secure find that they may be under notice to seek other accommodation which at the moment does not exist.

This unfortunate state of affairs could be greatly eased if the 56 houses presently occupied were all released and returned for their original purpose as professional premises. The present occupants of these houses, such as the Merchant Navy Club, Canadian Y.M.C.A. Club, and various branches of our Allies, could be equally and comfortably housed in a number of the many empty houses in Regent's Park. The same suggestion applies to the professional area in Mayfair.—I am, etc.,

London, W.1. Norman P. Henderson.

An Examination Paper for Nurses

Sir,—The current practice of adding to the nurse's curriculum studies on a par with those of a medical student has already evoked much protest from the profession. Apparently more is needed, and a signal addition is that of your correspondents (May 26, p. 751) who cite a recent examination paper. The corollary is obvious. One who studies enough to ensure passing such tests in medical subjects deprives her patients of proficiency in nursing.

Which is it to be? Nurses or pseudo-doctors? Let us insist that the General Nursing Council redresses the balance and gives pre-eminence to ward training in the practical *art of nursing*. If a girl has any wits a good sister will soon sharpen them: if she has not, then she may be ornamental but she is certainly useless to patients and should go. We are confronted with a deplorable dearth of nurses, and over-weighting the syllabus with medical science is calculated to aggravate the shortage. Let them get their simple studies over in a preliminary course and then get down undistractedly to what is their dominant interest—practical work in the wards. The sister will have a greater responsibility, and she must be chosen not only for outstanding quality as a nurse but after a year's postgraduate training to fit her for her duties as teacher also.

There is only one essential prerequisite for an entrant to the nursing profession, and when one is a patient one becomes painfully aware of it: not, Has she got the school certificate? but, Does she care? If she cares, she will soon master the technical side of her work.—I am, etc.,

Bristol. A. Wilfrid Adams.

Medical Students and Belsen Concentration Camp

Sir,—As the medical students from the London teaching hospitals are to-day leaving Belsen concentration camp I should like to take this opportunity of paying a tribute to the work that they have carried out during their stay. They arrived at a time when conditions in this horror camp were still indescribable; the first and only problem was the production of order and supervision of feeding in the huts to save the lives of those that had to wait their turn and to ensure the speediest evacuation of those that could be saved. The work of this type that they carried out is beyond praise, and entirely by their initiative a hospital area was formed in the original camp in which the worst cases that had to wait to the last were nursed and undoubtedly saved. Working, too, under the worst possible conditions, individual supervision of all the other huts was carried out and treatment where possible commenced. Later, when the whole camp had been evacuated, they were able to take full advantage of the wealth of clinical material available, and to carry out work of an entirely medical nature. This they did with equal zeal and enthusiasm.

The experience, apart from its medical side, has, I feel, given them a unique opportunity in that they were given the heaviest of responsibilities and their initial efforts depended entirely on their own initiative. One and all they threw themselves into the task with unbounded enthusiasm; they worked long hours in the worst possible conditions and never spared themselves. The results speak for themselves, and the fall in the death rate was, I am sure, largely due to their magnificent work. Thousands have cause to be grateful to them that their lives have been saved. The units of the R.A.M.C. in Second Army are no less grateful for the help that was so generously given.—I am, etc.,

Glyn Hughes, Brig.,
D.D.M.S., Second Army.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

Dr. W. L. H. Duckworth will retire from the position of Master of Jesus College on Sept. 30 under the age limit. After gaining first-class honours in Parts I and II of the Natural Sciences Tripos he was elected a Fellow of Jesus College in 1893 and in 1905 graduated M.D. and Sc.D. Dr. Duckworth was University Lecturer in Physical Anthropology 1898–1920 and Reader in Human Anatomy from 1920 until his election as Master of Jesus College in 1940. He represented the University for three years on the General Medical Council.

In Congregation on June 8 Prof. E. D. Adrian, M.D., F.R.S., was appointed to represent the University at the 220th anniversary of the Academy of Sciences of the Union of Soviet Socialist Republics in Moscow and Leningrad, June 15–28.

On the recommendation of the Faculty Board of Medicine additional qualifying examinations in anatomy and physiology will be held in December next, on dates to be fixed by the Board of Examinations.

During the month of May the titles of the degrees of M.B., B.Chir were conferred by diploma on Mrs. R. C. A. Hunter, of Newnham College.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At a meeting of Council, held on May 26, with the President, Mr. Eardley Holland, in the chair, the following were admitted to the Fellowship:

Caroline A. Elliott, E. A. Gerrard, R. J. Kellar, Meave Kenny, F. R. Stansfield. *In absentia:* G. S. Adam, A. M. Hill, J. J. Kearney, W. K. McIntyre, B. T. Mayes, H. K. Pacey, F. Stabler, G. A. Thompson.

The following were admitted to the Membership:

Amelia E. Burch, E. G. Collins, Jadwiga Karnicki, Gladys E. Keith, Dorothea M. Kerslake, Dorothy M. Shotton, B. G. G. Spiers. *In absentia:* J. P. O. Erskine, A. B. Hay, Sybil G. Mocatta, Dorothy J. Thompson.

At the annual general meeting of the College, held on May 26, with the President, Mr. Eardley Holland, in the chair, the following were elected to Council in place of those retiring by statutory rotation: *Representative of the Fellows:* Malcolm Donaldson. *Representative of the Members:* D. B. Fraser.

Obituary

W. L. SCOTT, *M.C.*, M.D.

We regret to announce that Dr. William Logan Scott, chief medical officer to the General Post Office, died at Winchester on June 1 after a short illness. He was born at Tollcross, in Lanarkshire, on Sept. 14, 1888, son of Alex Scott, M.D., and from Glasgow High School went to the University of Glasgow, where he graduated M.B., Ch.B. in 1911 and proceeded M.D. in 1934. After three years in house appointments at the Sheffield Royal Infirmary he became assistant M.O. at the Chelsea Infirmary in 1913 and then moved to the staff of the North-Western Fever Hospital, Hampstead. He served throughout the last war with the R.A.M.C. and was awarded the Military Cross. For two years after the armistice he worked as medical assessor to the Pensions Appeal Tribunal at the House of Lords, and then in 1921 became assistant M.O. to the G.P.O. at St. Martins-le-Grand. When Sir Henry Bashford left the G.P.O. to become Treasury Medical Officer in October, 1943, Dr. Logan Scott succeeded to the post of chief medical officer.

Sir Henry Bashford writes: The death, at the age of 56, after a tragically brief illness, of Dr. W. L. Scott, chief medical officer to the Post Office, will be most deeply deplored by the whole Department, which he had so faithfully served for more than a quarter of a century, both as clinician and administrator. He brought to his work a gay and breezy common sense, combined with a very wide and practical knowledge of his profession. He was associated with many researches in the sphere of sick absence in industry, particularly in respect of the subject of quarantine, upon which he had published two very valuable papers. He was also president of the Post Office Ambulance Centre. Scott was a man of wide interests and many hobbies—carpentering, painting, shooting—to all of which he brought a characteristic enthusiasm. He was the most delightful of companions in bright hours and dark, with an original wit and good spirits that never flagged; and he was the soul of kindness to all in trouble. For his widow and son the deepest sympathy will be felt by all who knew him.

GEORGE H. S. MILLN, M.B., CH.B.

Dr. GEORGE HERBERT STEPHENS MILLN, physician in charge, of the *x*-ray and electrotherapeutic department of the Dundee Royal Infirmary, was killed in a motoring accident on May 30 when driving to keep an appointment at the Adamson Hospital, Cupar, where he was honorary radiologist. He was born at Tayport in 1882, son of William Milln, an engineer officer of the Royal Navy. He graduated M.B., Ch.B. with second-class honours at the University of Edinburgh in 1903, and served as medical officer in the Navy until 1911. He retired with the rank of surgeon commander, R.N., on the Emergency List and was later posted as surgeon captain, R.N.V.R. He became an assistant in the *x*-ray department of the Dundee Royal Infirmary, and in 1926 was promoted to the visiting staff and made lecturer in radiology and electrotherapeutics in the University of St. Andrews. Dr. Milln was also medical officer in charge of radium at the Dundee Royal Infirmary, and honorary radiologist to the Arbroath Infirmary and the Dundee Dental Hospital and School. He joined the B.M.A. in 1913, had been treasurer of the Dundee Branch and of the City of Dundee Division, and held office as president of the Branch in 1937-8.

Dr. R. P. Mathers writes: The sudden tragic death of George Milln in a motor accident has taken from us a man of outstanding ability and popularity, whose cheery personality enlivened any gathering, whether social or professional. As a naval surgeon he served in many parts of the world until 1913. After his retirement he was appointed radiologist to Dundee Royal Infirmary, but in August, 1914, he again joined up and saw much active service, taking part in the Battle of Jutland. On his release with the rank of surgeon commander in 1920 he took up his work again as radiologist and gave constant and faithful service to Dundee Royal Infirmary and many other institutions in the district. In his early days the radiological department was a small affair, and Dr. Milln was mainly responsible for its rapid and extensive growth and reorganization to its present high standard of efficiency. His personal interpretation of skiagrams was always most practical and helpful, and the large circle of his colleagues who came into contact with him in the course of work will miss him greatly. He took an active part in the affairs of the B.M.A. His chief recreation was golf. The sympathy of all who knew him goes out to his bereaved wife and daughters.

We regret to announce that Mr. ROBERT SHARP LAWSON, honorary surgeon to the Leicester Royal Infirmary and president of the Leicester and Rutland Branch of the B.M.A., died on May 27. He entered the University of Edinburgh as an arts student and graduated M.A. in 1906, and four years later took the M.B. and Ch.B. degrees, with first-class honours. Having served as house-surgeon at the Edinburgh Royal Infirmary and the Royal Hospital for Sick Children, he was for some years demonstrator in the anatomical department and assistant in the pathological department of Edinburgh University. He held a commission as temporary surgeon, R.N., during the last war and obtained the F.R.C.S.Eng. diploma in 1916 after postgraduate study at St. Bartholomew's. On his return to civilian life he was appointed medical superintendent and surgical registrar at the Dreadnought Hospital, Greenwich. Settling in practice at Leicester Mr. Lawson was elected to the visiting surgical staff of the Royal Infirmary and became consulting surgeon to the Carlton Hayes Hospital. He was a Fellow of the Association of Surgeons of Great Britain and Ireland, a member of the British Orthopaedic Association, and a member of the Provincial Surgical Club of Great Britain.

It is now known that Dr. HERMANN BALEAN died on Jan. 19 of this year from acute anaemia at Stanley Internment Camp, Hong Kong, aged 69. He was a student of the London Hospital, where he won the Price entrance scholarship in science and a scholarship in anatomy and biology, the senior Letheby scholarship, and the Hutchinson prize. He graduated M.B.Lond. in 1901, M.D. in 1903, and B.S. in 1905, and obtained the F.R.C.S. in 1908 after serving as senior resident accoucheur and house-surgeon at the London Hospital. Dr. Balean was for many years honorary lecturer in anatomy at Hong Kong University and collaborated in papers on lupus erythematosus published in the *British Journal of Dermatology* and on the effects of acid on blood in the *Journal of Physiology*. He joined the B.M.A. in 1902 and was appointed a member of the Hong Kong Medical Board in 1937. With his wife he was interned by the Japanese after the fall of the island.

Dr. JOHN HALLY MEIKLE, who died on May 25 in an Edinburgh nursing home, was the second son of the Rev. Gilbert Meikle, of Inveraray. He entered Edinburgh University, and graduated M.A. with honours in 1889 and B.Sc. a year later; he then travelled by sailing ship to Australia round the Cape of Good Hope and spent several years teaching at a boys' school in Adelaide and fruit farming with his elder brother. He returned to Scotland in 1896 to begin the study of medicine, and qualified as M.B., C.M.Ed. in 1901. After practising for a short time in Edinburgh he became senior assistant and bacteriologist to the City Hospital, took the D.P.H. in 1904, and proceeded M.D. in 1906, with high commendation for his thesis. In the same year he was appointed to the newly created post of medical officer to the Edinburgh School Board, becoming responsible for the organization and administration of the school medical service from its inception until he retired in 1930. Dr. Meikle had been a member of the B.M.A. for over 40 years. He was one of the original members of the Edinburgh Medico-Sociological Society and took a great interest in its work.

Dr. LACHLAN GRANT, who died at his home at Ballachulish, Argyll, on May 31, was one of the senior medical officers in the Highlands and Islands Medical Service. He spent all his professional life (over 50 years) in the Highlands, and acquired a wonderful knowledge of Highland problems as they affected the Highland people. The writer of these notes was one of Dr. Grant's predecessors in Ballachulish in 1889-92. Lachlan Grant, whose home was then in Ballachulish, was a boy of 18. A friendship followed our first meeting, and, soon after, the boy told me that he wished to become "a doctor" if his father would permit him to remain in the Highlands and practise among the people. He chose Edinburgh University, and in 1894 graduated M.B., C.M. (with distinction), M.D. in 1896, took a D.P.H. in 1911, and later F.R.F.P.S. Glasgow. The prosperity of Ballachulish in those far-off days depended entirely on the flourishing slate quarries. A large number of men was employed on the "slate face." The men were an exceptionally fine type physically. They were intelligent and interested not only in slate quarrying as an art but in political problems connected with the Highlands. Lachlan Grant was not only a "good doctor" for them and their wives and children, he was also interested, they recognized, in Highland problems. And so it was that during his fifty years' service in Ballachulish, Glencoe, Kinlochleven, and Glen Etive, and the rest of that wonderful and historic piece of country, Lachlan Grant was the man to whom the people turned in adversity, for he was not only a skilful physician but a sympathetic friend and adviser. Ballachulish mourns his loss. To his devoted wife and family we offer our sympathy.—J. B. S.

The death has occurred at Middlesbrough of **JAMES RONALD McCURDIE** at the early age of 57 and after a long and painful illness bravely borne. Qualifying M.B., Ch.B. at Glasgow University in 1912 he spent two years as house-surgeon at Middlesbrough before joining the R.A.M.C. at the outbreak of the last war. He served throughout and was awarded the Military Cross, retiring with the rank of major. Returning to Middlesbrough he started in private practice and was soon appointed honorary surgeon to North Ormesby Hospital. Right up to the time of his death his hospital was the centre of his professional life, and he gave largely of his time and talents to its clinical and administrative affairs. He served on the governing council for many years as a representative of the honorary staff. He was largely responsible for the raising of the Home Guard in his district and was appointed its colonel. McCurdie had served for a period as chairman of the Cleveland Division of the British Medical Association, and was on its Executive for a number of years. For four years he was chairman of the Cleveland Local Medical War Committee, and brought to the conduct of its deliberations that care and grasp of its business which characterized everything he did. The funeral took place at St. John's Church, Middlesbrough, and was attended by many of his professional colleagues, by whom, as well as by a large circle of friends and patients, he is much missed. He is survived by his widow, to whom much sympathy is extended.

We regret to announce that Dr. **HAROLD JAMES PHILLIPS**, medical officer of health for Worthing, died suddenly at Southlands Hospital, Shoreham, on June 3 after a short illness. He studied medicine at University College, Dublin, graduating B.Sc., M.B., B.Ch. in 1920 at the National University of Ireland, and proceeding M.D. in 1927; he took the D.P.H. with honours in 1931. Dr. Phillips entered the public health service as assistant medical officer under the Kent County Council, was then deputy M.O.H. and school medical officer for the county borough of Hastings, and after that M.O.H., school medical officer, and medical superintendent of the isolation hospital of the borough of Ashton-under-Lyne. In 1938 he succeeded Dr. R. H. Wilshaw as M.O.H., school medical officer, and medical superintendent of the isolation hospital of the borough of Worthing. He was the author of a report on endocrine disturbances in school-children in Kent, and published in the *Medical Officer* a paper on faucial conditions as contributory factors in rheumatism. A memorial service at St. Paul's Church, Worthing, on une 8, was attended by the mayor, aldermen, and councillors, with the chief officers and staff of the Worthing Corporation.

The following well-known medical men have died abroad: Dr. **SALLES GUERVAN**, a leading surgeon in Rio de Janeiro during the first quarter of the present century, aged 75; Dr. **ASTROGILDO MACHAD**, head of the division of bacteriology of the Oswaldo Cruz Institute, aged 61; Dr. **ALEXANDER ACHILLE SOUQUES**, a leading Parisian neurologist, aged 89; Dr. **BERNARD CUNEO**, professor of surgical anatomy and surgeon to the Paris hospitals, aged 71; and Dr. **MAURICE PÉHU**, honorary physician to the Lyons hospitals and an eminent paediatrician.

The Services

Lieut.-Col. (Temp.) N. J. P. Hewlings, R.A.M.C., has been awarded the D.S.O. in recognition of gallant and distinguished services in North-West Europe.

Repatriated.—Capts. J. Graham Jones, R. P. Lawson, M.C., J. G. McGavin, G. B. D. Scott, and C. J. P. Seccombe, R.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Capt. **WILLIAM DONALD WILSON**, R.A.M.C., who was killed in action in Western Europe on April 24, went from Wigan Grammar School to Liverpool University, where he won the gold medal for surgery, the A. C. Rich prize, and the Lord Derby prize. After aduating M.B., Ch.B. and serving as house-surgeon at the Liverpool Royal Infirmary he joined the R.A.M.C. in 1943.

Medical Notes in Parliament

Wheat Germ in Flour

Sir E. GRAHAM-LITTLE asked the Minister of Food on May 15 what proportion of the flour used in this country was derived from wheat imported from abroad in the form of grain, not flour; what was the proportion of the whole stock of wheat germ distributed by the Ministry which was allotted to making bread; and whether flour which was supplied for biscuit and self-raising flour was deprived of wheat germ before that allocation was made.

Col. LLEWELLIN: The proportion of imported wheat used for flour milling varies from time to time in accordance with the supply position. The present proportion of imported wheat in all flour produced in this country is 47%. It is estimated that about 70% of the total available germ is in the flour supplied to the bakery trade for bread-making purposes, but a further considerable percentage is included in the flour used by confectioners and in flour used in the home for bread, confectionery, and other food purposes. The flour supplied specifically for the manufacture of biscuits and self-raising flour is "M" flour from which the germ has been removed.

Medical Demobilization

Sir JAMES GRIGG on May 29 told Major C. Taylor that the ordinary release regulations would apply to the R.A.M.C. as to the rest of the Army. He did not anticipate that the "military necessity" clause would be frequently applied to other ranks and general duty officers. It would probably have to be applied to specialist officers much more freely in view of the overall shortage of such officers and of the difficulty of obtaining from civil life replacements which were likely to be necessary. A number of doctors were due to be released under the ordinary working of the scheme. His difficulty was not of releasing doctors under Class B but of releasing those whose turn came under Class A. The need of the civil population for doctors was more likely to be met under Class B. It was a new idea to him that it would be necessary to have recourse to Class B for doctors.

Dr. HADEN GUEST suggested that where medical officers were to be released under Class B as essential for civilian needs, Sir James Grigg should ensure that their rights as regards 56 days' leave were safeguarded.

Food of German P.O.W.s

Sir JAMES GRIGG on May 29 repeated that non-working German prisoners of war had never received more of the nationally rationed items of food than civilians in this country. In view of the world-wide shortage of food it had been decided that the normal scale for these prisoners held by His Majesty's Government must be further reduced. Instructions had been issued for a new scale providing approximately 2,000 calories of all items, irrespective of whether these were rationed for civilians in this country or not. He said 2,000 calories was substantially less than the average civilian consumption in this country. Suitable additions of non-rationed foods, mainly bread and potatoes, would be made to cover the minimum extra needs of working prisoners. Otherwise they would receive the same scale as non-working prisoners.

Pneumoconiosis

Replying to a debate on May 29 (reported in these columns on June 9, p. 826) Major LLOYD GEORGE said he had been keenly interested in medical services since he went to the Ministry. On that subject the Government had laid down its policy in the White Paper, and the Ministry had, despite the shortage of medical men, made a start. It had another doctor at headquarters and another in each region. They would study local conditions, the local incidence of disease, and problems of that sort which they had been asked to investigate. The Ministry of Fuel was co-operating with the Medical Research Council on the arrears of examinations of men for pneumoconiosis and silicosis. They had been able, with the help of Sir William Jowitt, to double the panels working on pneumoconiosis. At the head of the panel was a man experienced in these diseases who trained the new man under him. He had a loan of a radiological unit, which would help in the matter.

Treatment after Discharge from Forces

Mr. STOKES opened on May 31 a discussion about the discharge of men from the Services before they had left hospital but when it had been decided that they were no longer of use to the armed Forces. He said this practice was particularly hard on men suffering from facial wounds, whose plastic treatment took a long time.

Mr. Petherick, replying for the War Office, said that if, after invaliding, a Service man still required treatment the Ministry of Pensions was notified under the continuity of treatment scheme and arrangements were made for the man's further treatment elsewhere. If the treatment had been given in an E.M.S. hospital the man could be retained there if that was in his medical interest. He might be transferred to a Ministry of Pensions hospital or an E.M.S. hospital nearer his home. When treatment had been given in a Ministry of Pensions hospital the man was retained in that hospital. These arrangements did not apply in cases of tuberculosis, nor to certifiable mental patients, who, when invalided, were transferred to the care of the responsible local authority. In most cases a final decision was reached in a few weeks or months on whether a man was going to be fit for return to active service. He then had a medical board. If found unfit for return he was discharged after 56 days. In place of his Service emoluments he passed to the appropriate rate of disablement pension and was handed over to the Ministry of Pensions. The Regulations provided that a man should continue on Service rates of pay for eight months. This might be extended to nine months in psychotic illness where further detention in a Government hospital might avoid certification. The period might also be extended until artificial limbs were fitted. It had been decided that men with tuberculosis might continue on Service emoluments for eight months while they received treatment in civilian or military hospitals. The period of eight months represented a considerable advance on previous practice. All cases of men disfigured facially had to be dealt with sympathetically, and the War Office was considering whether it could make some special arrangement.

Dr. Morgan said medical boards should come to a decision only when a man had reached the stage where the question was not of actual treatment but whether he should be passed from the Service Department to the Pensions Department. The men should be examined by independent medical boards, independent of Service remuneration and promotion.

Mr. Hopkinson inquired whether in Dr. Morgan's profession a certified medical man would give a wrong decision because he thought it was going to be to his advantage in a Government Department. Dr. Morgan said medical men were human and sometimes made mistakes. He made no charge against the profession.

Medical Enlistment and Demobilization

In reply on May 31 to Major Haden Guest, Mr. Willink said the numbers of medical men and women recruited from Great Britain and Northern Ireland into the medical branches of the Services up to May 24 last were 2,405 in the Royal Navy, 12,200 in the Army, and 2,564 in the R.A.F., making a total of 17,169. The figure for the Army included a number recruited for work with the Indian Medical Service. The proportion of the total number recruited to the total on the *Register* was 27.5%. The proportion of the number recruited to the total of active practitioners was 31.3%. The proportion of general practitioners in the Services was 21.4%. Mr. Willink said he was not yet able to state the number of medical men and women expected to be demobilized in the first six months after June 18. That depended on various factors, including the decision of the Service Departments whether an officer's retention was necessary on military grounds.

Mr. Palmer inquired whether any civilian doctors were to be called up. Mr. Willink said he did not like to reply on that point, but it might be right and just that those who had not been out should take their turn.

Medical Personnel (Priority) Committee

On May 31 Major Haden Guest further asked Mr. Willink to state the composition of the Medical Personnel (Priority) Committee and to say whether the work of this committee was to be continued. Mr. Willink replied that the Medical Personnel (Priority) Committee consisted of Sir Geoffrey Shakespeare as chairman, and twelve medical men representing the several branches of the profession and the Service Departments. The committee and its chairman had done most valuable work. There was no intention of bringing it to an end so long as general questions affecting the release and continued recruitment of doctors were still likely to arise for their consideration. Mr. Willink later circulated a list of the committee as follows:

Sir Geoffrey Shakespeare (chairman), Sir Girling Ball, Major-Gen. R. J. Blackham, Prof. J. Crighton Bramwell, Dr. J. A. Brown, Dr. W. M. Knox, Air Cdre. D. McLaren, Surg. Rear-Admiral A. E. Malone, Lord Moran, Prof. R. M. F. Picken, Prof. Sydney Smith, Mr. H. S. Souttar, and Sir Alfred Webb-Johnson.

Medical News

At a meeting of the Council of the Imperial Cancer Research Fund on June 7 Prof. H. R. Dean was reappointed chairman for the ensuing year and Sir Hugh Lett, Bt., was re-elected vice-chairman. The Council met at the laboratories of the Fund at Mill Hill and made a detailed inspection of the research work which is being carried out. Dr. L. Foulds was re-elected Elizabeth Wills Allen Fellow, and Dr. R. J. Ludford Alice Memorial Fellow. The Council received a letter from Mr. J. W. Johnson, of Stockport, accepting the office of Life Governor of the Fund.

The annual general meeting of the British Association of Physical Medicine will be held at 11, Chandos Street, W., on Tuesday, June 26, at 4.30 p.m.

The annual meeting of the Faculty of Radiologists will be held at the General Infirmary at Leeds on Friday and Saturday, June 29 and 30. The business meeting on Friday morning will be followed by a discussion on "The Treatment of Melanoma." In the afternoon papers will be read on "Advances in Radiological Technique." The annual dinner will be held at the Great Northern Hotel on Friday evening. Saturday morning will be devoted to a discussion on "Primary Malignant Tumours of Bone."

An exhibition of the care of the wounded entitled "Out from the Battle!" arranged by the Red Cross and St. John War Organization, with the co-operation of the War Office, is being held in the grounds of Clarence House, The Mall, London, S.W., from 11 a.m. to 7 p.m. on week-days and from 2 p.m. to 7 p.m. on Sundays until July 31. It was opened on June 12 by Lieut.-Gen. Sir Alexander Hood, D.G.A.M.S. The exhibition illustrates the work done for the British wounded by the Army Medical Services and the Red Cross and St. John War Organization.

The Royal Society for the Prevention of Accidents has issued from Terminal House, 52, Grosvenor Gardens, S.W.1, a provisional programme for the National Safety Congress which will take place in London on June 18–24. The main sessions will be held at the Institution of Civil Engineers, for discussions on post-war trends in industrial accident prevention, on group activities, and on the influence of training on accident prevention. The technical sessions will be held at the Industrial Museum, Horseferry Road.

The Queen has signed a message, as president of St. Mary's Hospital, warmly commending the scheme for the post-war reconstruction and extension of the hospital, which was founded 100 years ago.

A deputation from the National Association for the Prevention of Tuberculosis met the Secretary of State for the Colonies (Col. Oliver Stanley) on May 31 to discuss various matters connected with the prevention of tuberculosis in the British Colonies. The members of the deputation were the Duchess of Portland, chairman of council, N.A.P.T., Dr. R. A. Young, vice-chairman, Col. Walter Elliot, M.P., Prof. Lyle Cummins, Mr. H. A. Baker, treasurer, the Earl of Morton, and Dr. J. H. Harley Williams, secretary-general. Sir Austin Hudson, M.P., was unable to attend owing to Parliamentary duties. The suggestions discussed included the possibility of further surveys similar to a recent survey on tuberculosis in the West Indies promoted by the N.A.P.T., the offer of scholarships to colonial health officials for the study of tuberculosis work in this country, and the development of antituberculosis propaganda in the Colonies.

Twenty-five blind ex-prisoners of war were among the guests of Sir Ian Fraser, M.P., chairman of St. Dunstan's, at a luncheon in London on June 5, to welcome home from Germany Major David L. Charters, the Birkenhead ophthalmic surgeon, who had twice declined repatriation in order to continue his treatment of the men while in camp, and to thank Lord Normanby, who helped to organize the camp braille and the vocational instruction school which developed with the use of materials sent by the British Red Cross.

Alderman W. E. Jameson, M.B., C.M., Mayor of Hastings from 1940 to 1944, was presented on June 6 with the honorary freedom of the borough in recognition of his courage and devotion to duty during the war.

Dr. Edward Irving Pownoll Pellew succeeds his cousin, who died on June 7, as eighth Viscount Exmouth. The new peer, a great-grandson of the first viscount, was born on May 3, 1868, son of the late Capt. P. W. Pellew, R.N., and was educated at Clifton, Trinity College, Cambridge, and St. Bartholomew's Hospital, qualifying M.R.C.S., L.R.C.P. in 1901. During the last war he served with a commission in the R.A.M.C. as officer in command of 37 M.A.C. at Péronne on the Somme, and was awarded the O.B.E. and the French Ordre de Mérite Agricole. In recent years he has lived at Château de Bellevue, Larion, near Pau, in the Basses Pyrénées.

The Lord Mayor of London and the Lady Mayoress visited the Treloar Hospital at Alton on June 4, when a special ward block was named in memory of the late Sir Henry Gauvain, M.D., F.R.C.S. The Lord Mayor was received by the trustees of the hospital—Lord Burnham (chairman), Miss Florence Treloar, Sir Alexander Maclean, and Mr. William Baker—and members of the staff. The Bishop of Winchester offered a dedicatory prayer, after which the party went through the wards and special departments.

Mr. L. Graham Brown, F.R.C.S., has been adopted as the Liberal National candidate for Luton at the General Election; and Dr. H. B. Morgan is seeking re-election as Labour candidate for Rochdale. Dr. Guy Chandley Milner is standing as an Independent candidate for Orpington (Kent).

A luncheon was held in Nottingham on June 6 for the purpose of announcing the scheme to establish an East Midland Vocational Training College for the disabled. The initiating committee, formed from the Regional Orthopaedic Hospital at Harlow Wood, Nottinghamshire, has in mind to add to its work by establishing a vocational training college which shall cater for the ex-Service, ex-mine, and ex-industry disabled. Dame Georgina Buller described the work which on similar lines is being carried out at Exeter and at Leatherhead, where two colleges of this nature are under her foundation. A film depicting the training of the disabled was shown. The luncheon was attended by representatives of the British Legion, the Red Cross Society, and interested associations of the four counties, Derbyshire, Leicestershire, Lincolnshire, and Nottinghamshire, to whom an appeal is being made for the capital sum of £70,000. The building of this college will form the final stage in the plan for which Her Grace, Winifred, Duchess of Portland, was originally responsible in the area, and to which she has devoted a great part of her life.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* notifications were fewer in the following infections: measles by 2,718, whooping-cough 213, diphtheria 102, dysentery 60, and scarlet fever by 45.

Whooping-cough was less prevalent throughout the country, and most areas also showed a small fall in diphtheria, the 396 notifications being the lowest ever recorded; a fall of 21 cases in Yorks West Riding was the largest local decline. The fall in the incidence of measles was greatest in London and the surrounding counties, where the epidemic has persisted for some weeks longer than in the north; decreases on last week's totals were as follows: Surrey 286, Essex 216, Derbyshire 207, London 205, Southampton 183.

A large outbreak of dysentery occurred in Shropshire, where the cases rose from 0 to 57. The largest of the other returns were Lancashire 36, London 34, Staffordshire 31, Middlesex 27, Essex 23, Surrey 18, Warwickshire 18, Northumberland 16, Hertfordshire 15, Gloucestershire 14, Kent 10, Leicestershire 10, Yorks West Riding 10.

In *Scotland* measles notifications fell by 66 and those of whooping-cough by 55, while a small rise of 9 was recorded for scarlet fever, and for diphtheria 5. The total for dysentery remained almost unchanged: the largest returns were Glasgow 35, Edinburgh 23, Aberdeen 13.

In *Eire* whooping-cough notifications fell from 77 to 18. Twenty-three new cases of diarrhoea and enteritis were reported from Dublin C.B.

Quarterly Returns for Scotland

During the first quarter of 1945 there was a birth rate of 16.9, this being 0.9 below the average of the five preceding first quarters. Infant mortality was 68 per 1,000 registered live births, being 24 below the five-years average, and the lowest rate for any March quarter. Maternal mortality was 2.9 per 1,000 live births, and 0.1 above the rate for the first quarter of 1944, but 1.5 below the five-years average. The general death rate was 14.6 per 1,000, an increase of 0.7 over the first quarter of 1944, but 1.9 below the five-years average. Deaths from the principal epidemic diseases numbered 258, as compared with 390 in the March quarter of 1944. The chief causes of death under this heading were influenza 107, measles 44, whooping-cough 42, diphtheria 29, cerebrospinal fever 28. The death rate from all forms of tuberculosis was 81 per 100,000 and that from respiratory tuberculosis was 63, these rates being 6 and 4 respectively below the five-years average.

Week Ending June 2

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,233, whooping-cough 982, diphtheria 436, measles 10,455, acute pneumonia 486, cerebrospinal fever 44, dysentery 458, paratyphoid 8, typhoid 8. Three cases of typhus fever were imported.

No. 21

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended May 26.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945 (a)	1945 (b)	1945 (c)	1945 (d)	1945 (e)	1944 (Corresponding Week) (a)	1944 (b)	1944 (c)	1944 (d)	1944 (e)
Cerebrospinal fever	50	3	29	—	3	57	4	31	1	2
Deaths		—	1				—	1		
Diphtheria	396	24	132	73	16	507	21	126	58	25
Deaths	10	1	—	1	—	6	—	5	4	—

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London*.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Safe Dosage of Vitamin B

Q.—*A case has come to my notice in which the patient has been taking daily 200 mg. nicotinic acid and 3 pulvules of a compound containing 1 mg. of vitamin B_1 and 0.1 mg. of riboflavin per pulvule. This has been the daily dose for four months. Are there any dangers in large doses of vitamin B?*

A.—It is quite harmless. The total daily intake of B vitamins with these preparations would be 3 mg. of vitamin B_1, 0.3 mg. of riboflavin, and 200 mg. of nicotinic acid. The doses of the first two vitamins are within physiological limits, and although 200 mg. of nicotinic acid represents about ten times the daily physiological requirement, no harm is likely to come from the consumption of this quantity. If taken in one dose it may cause flushing of the face and pounding in the head, but these effects are quite transitory.

Adrenaline and the Heart

Q.—*What is the treatment of an overdose of adrenaline in a non-asthmatic subject? As some persons are very sensitive to adrenaline, what precautions should one take to minimize the risk, especially when using adrenaline in a local analgesic? As an overdose gives rise to all the symptoms of auricular fibrillation with acute or sudden onset, can this latter condition be caused in individual sufferers not receiving injections of adrenaline by an overaction of the supra-renals or by some alteration in their secretion? Has the quantity of adrenaline circulating in the blood of patients suffering from auricular fibrillation been tested?*

A.—The question appears to be based on a misunderstanding of some of the facts. The statement that an overdose of adrenaline gives rise to all the symptoms of auricular fibrillation is incorrect. It gives rise to violent palpitations, a very greatly increased force of heart beat, and an intense rise of blood pressure, but not to fibrillation. Only in combination with chloroform does adrenaline cause fibrillation, and then the ventricles are involved. It is the chloroform rather than the adrenaline which is to be blamed for this occurrence, and likewise, when cardiac irregularities follow the use of adrenaline together with a local analgesic, it is the local analgesic and not the adrenaline which is to blame. Adrenaline as a normal secretion of the suprarenal glands is a substance against which the body has its own method of protecting itself; this method is by rapid destruction. No steps more efficient than those which are taken by the body itself can be devised to deal with a sudden excess of adrenaline in the blood stream. Very large amounts of adrenaline (e.g., 15 minims of 1 in 1,000) can be injected intravenously into a cat without other effect than temporary collapse due to cerebral anaemia. There is no reason to suppose that an over-action of the suprarenals can lead to auricular fibrillation in a human subject. In tumours of the suprarenal medulla there occurs sudden liberation of adrenaline into the blood stream. The crisis is unpleasant, but is attended by nothing worse than palpitations and a temporary rise of blood pressure.

Staphylocoagulase

Q.—*Are all pathogenic staphylococci coagulase-positive? Would you give, for the benefit of the non-bacteriological reader, a brief description of the test and discuss its significance. Is there, for example, any connexion between the coagulase activity of staphylococci and the thick pus of staphylococcal infections?*

A.—The production of staphylocoagulase is by far the most constant character of *Staphylococcus pyogenes*, as well as being much more easily and rapidly demonstrable than any of the cultural characters on which reliance was placed in the past. To perform the test for it a tube containing a small quantity of sterile citrated plasma, which may be diluted if economy is desired, is inoculated heavily with the staphylococcus and incubated for up to four hours: a solid clot is formed, usually in less time than this, by positive strains.

Correlation between coagulase production and pathogenicity is almost perfect. When coagulase-negative strains are found in the presence of definite infection, some other cause for this should be sought, either in the shape of another bacterium or in some cause of lowered resistance to bacterial attack. The fibrinous nature of the exudate in staphylococcal infections is attributable to the action of staphylocoagulase in the body.

Haemorrhagic Tendency in the Newborn

Q.—*A newborn child developed the first day of his birth symptoms of cerebral haemorrhage, the diagnosis being confirmed by a lumbar puncture; the child died the third day after birth. Delivery was normal, easy, and no instruments were used. The father and mother are young and healthy and have no syphilitic antecedent or symptoms. This was their first child, and they are anxious in case the tragedy should occur again. What might have been the cause of the cerebral haemorrhage, and what prophylactic treatment might be used?*

A.—With the early development of bleeding, such as is described in this case, the cause must be regarded as trauma in the widest sense rather than any haemorrhagic tendency, which tends to develop after the first day. It should be remembered that some degree of moulding of the foetal head occurs even in the most normal of labours, and hence a tentorial tear *may* be found despite the essentially non-traumatic nature of the delivery described for this case. The chances of this recurring are very small, whereas the haemorrhagic tendency is liable to be a familial complaint. But it would be wise, in view of this history, to use in any subsequent labour a prophylactic dose of vitamin K. This should be given to the mother as 20 mg. of a synthetic analogue not less than 2 and not more than 12 hours before delivery, and the baby should also be given a dose of 0.5 to 1 mg. after birth. It may be fair to comment on this case that the mere finding of blood in the cerebro-spinal fluid does not necessarily establish a diagnosis of intracranial haemorrhage, and in any case it is a procedure fraught with a certain amount of danger for an already ill baby.

Gargling as Prophylaxis

Q.—*Is there any medical reason for gargling as a prophylactic measure (i.e., any evidence that it is of any benefit at all)?*

A.—We know of no evidence that gargling with anything will protect against a prevalent air-borne infection. Its effect must obviously be so transitory that very frequent repetition would be the only logical way of employing it for this purpose.

Treatment of Smallpox

Q.—*Does the injection of soluble liver extract hold any place in the treatment of smallpox? Some months ago an Indian colleague informed me that a single injection of 1 to 2 c.cm. of a liver extract, administered early in the disease, prevented pustulation, thereby shortening the duration of the illness, preventing scarring, and diminishing the severity of general manifestations.*

A.—The validity of this claim could be tested only over a large series of cases of variola major with suitable controls. Minimal pustulation and subsequent scarring in smallpox is a natural phenomenon in partial immunes—hence the value of any remedy is very difficult to assess over a small number of cases. Sulphonamides might be expected to limit the amount of secondary infection of skin lesions, but the answer to this, too, requires considerably more experience than has been available in this country.

Treatment of Dental Abscess

Q.—*Why do so many dentists refuse to extract a carious tooth with abscess until the swelling has subsided? Is such delay ever justifiable?*

A.—Adequate drainage of an alveolar abscess must be obtained, and if this can be done only by the extraction of the tooth concerned then the tooth must be sacrificed without delay. It is quite justifiable at times to attempt to save a front tooth if the abscess can be drained through the root canal. Many dental abscesses, by the time they are seen by the dental surgeon, have already pointed through the alveolus and are discharging or are about to discharge into the mouth, and it may be wise in these cases to wait until the swelling has subsided and the patient's general condition has improved before removing the tooth.

Local analgesics are contraindicated in these cases, and when the dentist has not the advantages and facilities of immediate general anaesthesia he may well be tempted to wait a few hours if he has reason to think that drainage will occur spontaneously.

Non-specific Asthma

Q.—*A man of 50, employed before the war as gardener-handyman, suffered from asthma apparently due to fumes in coke-boiler-house. During the war he has been in the N.F.S. and was free from asthma. On resuming his old employment the asthma has returned. It is not a garden reaction, for he continued gardening while in the N.F.S. He is anxious not to lose his present job. Can anything be done to help? Would a gas-mask be of use?*

A.—Some sufferers from hay-fever are relieved by breathing through a gas-mask and the same might well be true of the present patient. The fumes of the coke-boiler-house are presumably non-allergic and release a latent asthma in a non-specific way, as exertion or emotion might. It is therefore unwise to conclude that the patient is not sensitive to something in his work or place of employment, and it would be better to consider all possible causes for his asthma quite dispassionately, as asthma is so often multi-determined.

Function of Alkaloids in Plants

Q.—*Is anything known of the natural part played by the various alkaloids isolated from plants? What, for example, is the physiological action of the opium alkaloids in the poppy?*

A.—The significance of alkaloids for the plants that form them has been the subject of much discussion. Since they have never been shown to have any direct effect in the plants' economy, their alkaloids are usually regarded either as waste-products of protein degradation (analogous to urea in animals) or as nitrogenous reserves. Alkaloids of complex constitution, such as the morphine group, which remain undecomposed at the death of the plant, or which are "excreted" by abscission of parts such as leaves, can only be considered as waste products. Alkaloids, usually of less complex constitution whose formation is reversible like hyoscyamine and nicotine, are spoken of as "reserves." The very low concentrations in which they occur must prevent them from being of much significance. The "survival value" attaching to their toxicity to grazing animals also appears to be of little practical importance. The presence of alkaloids in certain plants is due to their possession of unusual enzymes. Any results of this metabolic kink are secondary, and so far as can be said at present none of them is important.

Habitual Abortion

Q.—*A woman aged 31, with a child 2½ years who was six weeks premature, has in the last six months had two miscarriages at three months, both of which were thought to be due to a retroverted uterus. The first occurred a few days after the retroverted gravid uterus had been replaced. Two weeks after the miscarriage the uterus was found to be in a normal position. During the last pregnancy, examination was carried out two weeks after the first menstruation was missed; the uterus was found to be retroverted and was replaced. Miscarriage occurred 10 days after the third menstruation was missed. The uterus was palpable per abdomen just before abortion began. On both occasions there had been slight haemorrhage at the second month. The first child was born in the Tropics; the first miscarriage was in South Africa, and the last in the Tropics. What advice would you give about future pregnancies? Even if a Gilliam was thought advisable, it could not easily be done in the Tropics. Should a Hodge pessary be used when pregnancy starts, or even before? Would hormone therapy help, and how should it be carried out? Or would the miscarriages more likely be due to the abnormal position of the uterus? The patient is healthy and anxious to start another pregnancy soon.*

A.—Retroversion, dating from the first puerperium, is a possible factor in the causation of the abortions, but it can hardly be the only one, because the position of the uterus was corrected in the third pregnancy and yet abortion occurred several weeks later. Moreover, it is difficult not to associate the premature labour with the two abortions and to regard it as additional evidence of an "abortion habit." If no general disease or other local abnormality can be found then treatment must be largely empirical. Another pregnancy should be deferred until six months after the time of the last abortion. The retroversion should be corrected and a Hodge pessary fitted just before conception is attempted. If all goes according to plan the pessary should not be disturbed until at least the sixteenth week of pregnancy, when it should be gently removed with a minimum of interference to the uterus. Apart from this, vaginal manipulations or examination should be avoided once pregnancy has occurred. Twice-weekly intramuscular injections of progesterone should be begun as soon as the first period is overdue and continued until the thirty-second week of pregnancy. Thyroid gr. 1 nocte, and vitamin E 3 mg. b.i.d., might also be given throughout pregnancy, and an adequate intake of iron, calcium, and the other vitamins assured. The patient should be instructed to live as quiet a life as possible, avoiding, in particular, coitus, riding in mechanically propelled vehicles, horse-riding, and heavy work.

Although quinine does not ordinarily cause abortion, it might in a susceptible individual; so if the patient lives in a malaria district and takes this as a routine, the possibility should be kept in mind.

Spina Bifida Occulta

Q.—*A female child now aged 2½ years was operated on one year ago for spina bifida occulta. No attempt to crawl or walk had been made; there had been attacks of diarrhoea and pyelitis. The bladder was distended and dribbled every few minutes. The child had appeared normal in every respect up to the age of 9–10 months. At operation a mass was found in the lower end of the spinal canal attached to the conus, which extended to the bottom of the theca. The nerves appeared normal. The posterior portion of the mass was removed and microscopically was found to consist of normal nerve tissue and distorted nerve tissue plus an area suggesting central canal tissue. Shortly after operation the child began to put on weight and to crawl. She is now able to walk about 100 yards with assistance. Dribbling of urine continues as before. In addition there is no control over the anal sphincter now. The anus is often half open and small pieces of faeces are passed 7 or 8 times daily. For the past six months electrical treatment in the form of a direct galvanic current has been carried out to legs and anus. The urine is kept acid and a strict watch is kept on the child's general health, which is excellent. Can any further curative or prophylactic treatment be carried out? What has been the history of similar cases? Is there a possibility that sphincter control may develop? What references are there in the literature to such cases?*

A.—Spina bifida occulta does not as a rule cause symptoms so early in life as in this case. The early symptoms may have been due to the extended growth or adhesion of the conus. Inasmuch as walking has improved since the operation it is possible that further improvement may occur in the matter of sphincteric control, though Elsberg states that in his experience "long-existing bladder disturbances due to spina bifida occulta have been little benefited by surgery." On the other hand Stockmeyer mentions the case of a girl aged 6 suffering from spina bifida occulta accompanied by incontinence of urine and faeces and weakness of the legs in whom control over the urine and faeces was regained merely by rest in bed. I have been unable to find any exactly similar case to that narrated in the question, but clearly no further operative treatment is indicated, and the best procedure would seem to be to continue the excellent measures at present being carried out. Reference may be made to Elsberg, C. A., *Surgical Diseases of the Spinal Cord*, 1941, p. 184, New York; Stockmeyer, Karl M., *The Value of the Surgical Treatment of Spina Bifida*, 1925, Berlin; Ingraham, F. D., and Swan, H., *New Engl. J. Med.*, 1943, **228**, 559.

Certifying Sanity

Q.—*How can a person who was certified some years ago, and who was "relieved" after three weeks in a mental hospital, be certified as sane?*

A.—There is no statutory certificate of sanity in England or Scotland. A certificate signed by one or more registered medical practitioners stating that in their opinion a named person was sane at the date of the certificate has no more and no less value than any other medical certificate. It is admissible as evidence in a court of law without the appearance of the signatory only if he is dead, or unable to attend, or out of the country, or untraceable, or if to call him would cause undue trouble or expense.

Antispasmodics for Whooping-cough

Q.—*In view of the laryngeal spasm so important in pertussis, has adrenaline ever been used in treatment, and, if so, with what results?*

A.—Antispasmodics have been extensively used in whooping-cough. Ephedrine is normally preferred to adrenaline for its more prolonged effect and the fact that it can be given by mouth. A suitable preparation is the elixir ephedrin. hydrochlor. with the dose adjusted to allow ephedrine gr. 1/4 twice a day for a child of 1 year and a corresponding reduction for younger children. Generally speaking, antispasmodics are disappointing in whooping-cough. Further, children do not tolerate ephedrine particularly well, and it should be used with caution.

Idiopathic Pigmentation

Q.—*A male patient has a patch of light brown discoloration on his forehead, extending the whole length of the forehead and about 1 in. in breadth. It appeared after wearing a metal eyeshade to protect his eyes from the glare of the electric light in his office. The metal of the shade was in direct contact with the skin of his forehead. There is no erythema and no scaling; no pain or itching; no evidence of pityriasis capitis or seborrhoea. Scraping shows no fungus present. Soothing lotions—e.g., lot. calaminae oleos. cum ichthyol.—have been applied with no success.*

A.—As the duration of the condition is not mentioned nor when the eyeshade was discontinued, idiopathic pigmentation cannot be excluded. Various metals, especially nickel, are potential skin irritants and may cause both irritation and pigmentation. It is assumed that the patient has not lived in the East. Bathing with peroxide of hydrogen 10 vols. may succeed, or application of 1 in 1,000 perchloride of mercury lotion.

INCOME TAX

Recommencement of Work

P. H. was away from work through illness for one and a half years, restarting in October, 1942. He has been assessed as follows:

Year to April, 1943: On the amount of the profits for the six months to April, 1943, £x
„ „ 1944: On the amount of the profits for the year to October, 1943, £x + £y
„ „ 1945: On the amount of the profits for the year to October, 1944, £y + £z

He points out that this means that £x and £y have entered twice into the calculations and asks if this is correct.

⁂ The basis above is legally correct—assuming that P. H. restarted work as a practitioner on his own account. It has to be remembered that the previous year's profits are adopted only as a basis of assessment. In fact when P. H. has paid the tax assessed for 1944–5 he will have paid tax for the 2½ years to April 5, 1945, and have paid on 2½ years' profits only. If he should find that his profits for 1944–5 were smaller than the amount of the assessment, he should consult the inspector of taxes as to an adjustment to the "actual" amount. There is no provision in the Income Tax Acts for any relief in respect of the period when P. H. was unable to carry on his professional work.

Earnings of Married Woman

W. M. has about £20 a month deducted from her salary of £600 a year. Is this correct?

⁂ Yes, if her husband's income is sufficient to cover the whole of the allowances to which he is entitled—i.e., £140 as a married man, £100 in respect of two children, and the earned income relief, and the £165 chargeable at the lower rate. If his income, as correctly assessable, is below, say, £450, the matter should be raised with the inspector of taxes on the ground that the *husband's* income has apparently been over-assessed.

LETTERS, NOTES, ETC.

A New Covering for Skin Dressings

Dr. J. E. M. Wigley writes: In answer to Dr. R. Stopford-Taylor's comment (June 2, p. 794), I think he has missed the point of my note. Stannard silk is a different product from the old "green protective" oiled silk in that it is impregnated with a special synthetic resin. This renders it incapable of sticking to moist and other surfaces, as I pointed out in my note—a property which I have not found possessed by ordinary oiled silk. Still, I agree with Dr. Stopford-Taylor's implied quotation, "There is nothing new under the sun."

Radium for Mooren's Ulcer

Dr. A. J. Durden Smith (Northwood, Middlesex) writes: In your issue of May 5, under "Any Questions?" there is a question asked about the treatment of Mooren's ulcer. I find myself entirely in agreement with the answer except with the statement that the application of radium "has been suggested." This is surely rather an understatement of the case. I have myself treated many cases of this condition by radium with varying results, but with some undoubtedly good ones. The damage of the ocular apparatus from the beta rays of radium is, I think, negligible. I only write because this is a condition which, as the answer suggests, is hardly amenable to any form of treatment, and this form of radiation does offer a chance of cure in a certain number of cases.

Perionychia

Dr. H. G. Langdale-Smith (Hereford) writes: In "Any Questions?" (*B.M.J.*, May 19) the question of treatment of perionychia is raised. For some time I have treated this condition by a combination of Bier's induced hyperaemia and sulphonamide therapy, and this has superseded all other troublesome procedures. One gramme or more of a suitable sulphonamide is given at 10 a.m., 2 p.m., and 6 p.m. At midday, 4 p.m., and 8 p.m. a constricting band is applied to the arm of the affected hand, which is immersed in warm Dakin's solution for 10 to 15 minutes. This is repeated in a week's time. Whether the concentration of sulphonamide in the blood of the fingers is increased by this method I do not know, but the effect is generally very satisfactory.

Treatment of Inevitable Abortion

Dr. Josephine Barnes (London, W.C.1) writes: May I join issue with you on the question on "inevitable abortion" (May 26, p. 757). I agree in principle, but I cannot help taking exception to the remark in the first paragraph: "Oxytocin (5 units intramuscularly) is perhaps preferable to pituitrin." Prof. Chassar Moir, acknowledged as the greatest living authority on this subject, I think, states in his critical review on oxytocic drugs and their use (*J. Obstet. Gynaec. Brit. Emp.*, 1944, **51**, 247) that for the aborting uterus "a greater effect can be obtained from the use of 'normal' extract than from the purified oxytocic fraction." He elaborated this point further in the article. I think it is not generally realized that oxytocin (pitocin) is relatively inactive in early pregnancy in the intact human uterus. See also your annotation on Prof. Moir's paper (*Journal*, Dec. 16, 1944, p. 796). I also disapprove strongly of active intervention in infected cases. I always leave them alone unless there is dangerous haemorrhage, because of the risk that interference may spread the infection.

X-ray Treatment of Dupuytren's Contracture

Dr. Bernard Leggett (Forest Gate, E.7) writes: On page 793 of your issue of June 2 I note *x*-ray therapy is advocated for the above condition. In the boom of ultra-violet-light treatment in the nineteen-twenties ultra-violet light was advocated for *x*-ray burns, in spite of the strong probability that the effects of electromagnetic waves with varying time for erythema production would be cumulative. Even after Phaler in the U.S.A. by animal experiments showed that ultra-violet light accelerated *x*-ray burn changes, ultra-violet light was still advocated for *x*-ray burns. I suggest that whoever is responsible for your journal publicly advocating *x*-ray treatment for Dupuytren's contracture carries out *x*-ray treatment as a "cure-all" rather than on rational grounds. Conditions amenable to *x*-ray treatment are widespread, but I have always grouped such conditions as (1) those where *x*-ray treatment is the method of election—i.e., acne, (non-cystic) thyroid hyperplasia, warts, etc.; (2) those conditions of varying causation, such as pruritus, where there is reasonable chance of success and the attempt is warranted; (3) those conditions where there is no histological reason to expect good results; and (4) conditions where *x*-ray treatment is definitely contra-indicated. I would place Dupuytren's contracture in the last category, and some months ago, when a professional patron rang me to inquire respecting my treating a Dupuytren's contracture, I declined the case. It has been advocated by many that the real effect of *x*-ray treatment is very simple—i.e., that in most cases the effect is to cause irritation and induce fibroblastic reaction, so that with acne the skin is "hardened" by the formation of connective tissue and, in the thyroid, the adenomatous tissue is restricted by the formation of connective tissue. Since Dupuytren's contracture is due to the excessive growth of connective tissue, there would appear to be no more adverse treatment possible than to give *x*-ray treatment.

Head Rupturing through the Perineum

Dr. Margaret B. Fox writes from the Duchess of Teck Hospital, Patna, Bihar: An Indian girl of 19 years, a primipara, was admitted to hospital on February 25, 1945. She was in labour, and ten minutes after admission the membranes ruptured and the head appeared at the vulva. The vulva did not dilate up normally, but a rupture appeared in the posterior part of the perineum, which rapidly increased in size with the bearing down of the head. A median episiotomy was performed and the baby delivered. The rectum was intact and the levator muscles widely separated in the midline, leaving smooth edges. The mucous membrane was torn, up to the cervix. The tear was repaired in the usual way, and the patient went home on the 14th day. The measurements of the bony pelvis were quite normal.

Penicillin and Other Drugs

Major C. F. Garfit (Lahore) writes: I read the medical memorandum on penicillin in ophthalmic therapeutics by Major A. J. Cameron (Feb. 17, p. 222) with interest, as this is the first time I have seen reference made to the effect of penicillin on the drugs commonly used in ophthalmic practice. As regards Major Cameron's findings with adrenaline hydrochloride, it at once occurred to me that in making his experiments perhaps he used the liq. adrenalin. hydrochlor. *B.P.* or a similar preparation. This preparation contains 0.5% chlorbutal and so possibly this substance might have played its part in the result; 0.3% free dilute hydrochloric acid is also, of course, present. While for practical clinical purposes his result is the one that counts, since liq. adrenalin. hydrochlor. *B.P.* is the preparation normally used, nevertheless the point seems to be of some interest. Perhaps Major Cameron could kindly clear up this point.

Medical Golf

The Stratford Division (B.M.A.) Golfing Society has arranged a competition for the Scottish Bowl to be held at Thorndon Park on Thursday, Sept. 27. The competition is open to all golfers in the Division who are members of the B.M.A. There is no annual subscription for 1945. The hon. sec. is Dr. A. J. Buchan, 69, Belmont Road, Ilford. (Tel.: Ilford 0555.)

Correction

A mistake in the review of *Human Embryology* (June 9, p. 808) must be corrected. The opening words in the last sentence of the second paragraph should of course read "The inclusion of sections on foetal *physiology*. . . ."

BRITISH MEDICAL JOURNAL

THE TOXICITY OF 2,2-*bis* (*p*-CHLORPHENYL) 1,1,1-TRICHLORETHANE (D.D.T.)

BY

G. R. CAMERON, M.B., D.Sc.Melb., F.R.C.P.

Professor of Morbid Anatomy at University College, Hospital Medical School in the University of London

AND

F. BURGESS

The introduction of the new synthetic insecticide 2,2-*bis* (*p*-chlorphenyl) 1,1,1-trichlorethane (D.D.T.) demands that possible hazards to man be determined and potential dangers safeguarded against. We describe in this paper investigations on the toxicology of D.D.T. which we carried out during the period April, 1943, to March, 1945. These have been the subject of several reports to the Ministries of Production and of Supply, at whose request we have prepared the following account.

Methods

Our material embraces a variety of laboratory animals as well as human volunteers. Toxic effects and fatal doses (L.D.50) were determined in rats, guinea-pigs, and rabbits, D.D.T. being administered by various routes, in single or repeated doses, and dissolved in a number of solvents. Both crude and pure samples of D.D.T. were employed ; the former is said to contain 5% sulphuric acid, but appears to behave similarly to pure D.D.T. Some experiments on the action of D.D.T. powder on healing of experimental wounds were also done. Human experiments were chiefly confined to the wearing of garments and underclothes impregnated with D.D.T. In all cases a close watch was kept for the development of toxic effects, and exposed animals were the subject of careful pathological examination at death or when the observational period had elapsed. Various investigations were made on selected subjects, including blood and urine examination and body-weight determination throughout the course of exposure. These will be described in the appropriate sections. Necropsies on animals were performed immediately after death or, frequently, when the animals were moribund. Microscopical examination of all the important organs and tissues, including the central nervous system in representative cases, followed upon preparation of paraffin and frozen sections. Tissues were fixed in 10% formol-saline and 10% formol-alcohol, embedded after passage through the alcohol series, and many sections stained with Ehrlich's acid haematoxylin and eosin and Weigert's iron haematoxylin and van Gieson as a routine procedure, and often with Heidenhain's azan method, v. Kossa's method for calcification, the prussian-blue method for iron, Weigert's elastica method, and Turnbull's Jenner method for bone marrow. The Scharlach-R fat stain was employed with frozen sections after 10% formalin fixation. The central nervous system was dissected out with very great care so as to avoid disturbance of relationships and trauma from handling. After prolonged fixation in 10% formol-saline, transverse wedges of tissue, a few millimetres thick, were removed at the level of the anterior third of the frontal lobes, at the level of the hypophysis, through the middle of the cerebellum and pons, and at the commencement of the medulla. Such wedges included the whole of the cerebral tissues in a cranio-caudal direction. Paraffin sections were stained with the usual haematoxylin and eosin and van Gieson methods, with toluidine blue, and with the Marchi method. Sections from the main levels of the spinal cord were also prepared from a limited number of animals.

ANIMAL EXPERIMENTS

Single Doses.—Single doses of D.D.T. were administered to groups of at least 5 animals by skin application—the skin area being shaved 24 hours previously—by stomach tube, and by subcutaneous and intramuscular injection. For skin application we used solutions of D.D.T. in ether, kerosene, dimethyl phthalate, and dibutyl phthalate. The two latter solvents have their uses in insect control. For gastric and subcutaneous administration we dissolved D.D.T. in medicinal liquid paraffin and a small amount of tragacanth. About 400 animals were used in these experiments. For skin application of single doses the L.D.50 for our rabbits was 300 mg./kg., for guinea-pigs 1,000 mg./kg., and for rats 3,000 mg./kg. Results were in close agreement when ether and kerosene were used as solvents. For subcutaneous injection the L.D.50 for rabbits was 250 mg./kg., for guinea-pigs 900 mg./kg., and for rats 1,500 mg./kg. Liquid paraffin was the solvent. For gastric administration the L.D.50 for rabbits was 300 mg./kg., for guinea-pigs 400 mg./kg., and for rats 800 mg./kg. Control animals given the largest amount of solvents used in the above tests, but without D.D.T., were unaffected. Results of tests in which dimethyl phthalate and dibutyl phthalate were employed as solvents were substantially in agreement with the above, though we did not carry out subcutaneous tests. Although the L.D.50 levels were definite enough in most cases, a certain number of animals died after doses lower than these levels. Generally speaking, the lowest dose which produced some casualties was about half to two-thirds that of the L.D.50. Even so, it is apparent that the toxicity of D.D.T. when given in solution by various routes as single doses is not high.

Repeated Administration of D.D.T.—Repeated skin application of D.D.T. has been carried out with various solutions and emulsions of D.D.T., with the dry powder, alone or mixed with pyrophyllite, and through the agency of impregnated cloth. The effect of repeated gastric administration has also been investigated, and some experiments in which animals were frequently exposed to heavy mists of D.D.T. in chambers were performed. Precautions against licking contaminated skin were always taken.

1. Solutions or Emulsions

(i) 10% Kerosene Solution.—Five rabbits were given daily skin applications of 100 mg./kg. D.D.T. as a 10% solution in kerosene; 5 guinea-pigs and 5 rats received 200 mg./kg. All of the rabbits were dead after 6, the guinea-pigs after 12, and the rats after 14 applications. All showed clinical features of D.D.T. poisoning and severe inflammation of the skin.

(ii) 1% Kerosene Solution.—Five rabbits, 5 guinea-pigs, and 5 rats were given daily applications, each 2 hours in duration, of 50 mg./kg. D.D.T. as a 1% kerosene solution. No rabbit survived more than 16 applications, no guinea-pig more than 18, but only one rat died during a series of 20 applications. Nervous symptoms were uncommon, but fatal cases showed severe liver damage. Skin irritation occurred in all. Similar groups of rabbits, guinea-pigs, and rats received daily applications of 10 mg./kg. D.D.T. Rabbits survived 20 such exposures without clinical signs of intoxication, and no pathological changes were found when they were killed off. Skin irritation, however, was present. Two guinea-pigs died after 11 applications, both showing moderate liver damage. The other three received 14 applications without ill effects. None of the rats were affected by 14 applications. Control experiments with kerosene alone showed that skin irritation developed and sometimes animals died from this. It is obvious that kerosene may have accounted for some of the deaths in the above experiments. This was more especially the case with rabbits.

(iii) 1% Ethyl Alcohol, Acetone, and Ether Solutions.—Groups of 5 rabbits, 5 guinea-pigs, and 5 rats received daily applications, each lasting 2 hours, of 10 mg./kg. D.D.T. as 1% ethyl alcohol, acetone, or ether solution. With ethyl alcohol as solvent, 2 of 5 rabbits died after 9 and 12 applications respectively; with acetone as solvent, 1 of 5 rabbits and 2 of 5 guinea-pigs died after 7, 7, and 9 applications respectively; with ether as solvent, 1 of 5 rabbits and 2 of 5 guinea-pigs died after 13, 7, and 8 applications respectively. No rats died during the experimental period of 14 applications. All fatal cases showed moderate or severe liver damage but no nervous symptoms.

(iv) Emulsions.—(*a*) Emulsion I (Geigy), composed of 15 parts D.D.T., 30 parts toluene, 15 parts hexamethylenetetramine, 36 parts sulphonated castor oil, and 4 parts ammonia, was diluted 1:100 with water. Five rabbits, 5 guinea-pigs, and 5 rats received 14 daily applications each of 5 c.cm./kg. diluted emulsion (about 7.5 mg./kg. D.D.T.). Two guinea-pigs died from intercurrent infection after 14 applications. No clinical features of D.D.T. intoxication were seen in any of the animals, and the skin at the site of application was not inflamed. At the termination of the experiment all animals were killed and their main organs examined microscopically, but no pathological changes were found.

(*b*) Pymulso concentrate Mark X, containing 1% w./v. D.D.T. and about 0.2% pyrethrins, diluted 1:10 with water, was applied on 12 occasions in daily doses of 5 c.cm./kg. to the skin of 2 rabbits, 4 guinea-pigs, and 6 rats without giving rise to any evidence of skin irritation, intoxication, or pathological change in their organs.

(*c*) Pymulso concentrate Mark XI, containing 2% w./v. D.D.T. and 0.4% pyrethrins, diluted 1:20 with water, was applied in daily doses of 5 c.cm./kg. on 12 occasions to 2 rabbits, 4 guinea-pigs, and 6 rats. No ill effects were observed in the skin or organs when the animals were killed at the end of the experiment.

(*d*) Pymulso special, containing 0.5% w./v. D.D.T. and 0.02% w./v. pyrethrins, was applied on 5 occasions in doses of 5 c.cm./kg. (25 mg./kg. D.D.T.) to the skin of 5 rabbits and 5 rats. Although no symptoms of D.D.T. intoxication developed, the skin became severely irritated. Experiments were discontinued at this stage. Microscopical examination of the main organs disclosed no pathological change attributable to D.D.T.

(*e*) Special pymulso concentrate, containing 10% w./v. D.D.T. and 0.4% w./v. pyrethrins, diluted 1:20 with water, was applied on 15 occasions in doses of 5 c.cm./kg. to the skin of 5 rabbits and 5 rats. Each application, equivalent to 25 mg./kg. D.D.T., lasted 2 hours, after which the emulsion was removed with water. No inflammation of the skin developed, and the animals appeared normal throughout the experimental period. They were killed and their organs examined microscopically, but no pathological changes attributable to D.D.T. were found.

It is apparent from these experiments that the manner of preparing the D.D.T. suspensions is important for toxic effects and that some of the pymulso suspensions are more suitable than others.

2. D.D.T. Powder

Groups of rabbits, 4 animals in each group, were given 16 daily applications of 50 mg./kg. and 10 mg./kg. D.D.T. powder on the shaved skin of the back. Each application lasted two hours. During the experimental period no symptoms developed, there was no loss of weight, and the organs and skin showed no pathological changes when examined microscopically at the end of the experiment. Three rabbits, 3 guinea-pigs, and 3 rats received 9 daily applications, each of 2 hours' duration, of dry 5% D.D.T. in pyrophyllite, in doses of 200 mg./kg. (i.e., 10 mg./kg. D.D.T.) for rabbits and guinea-pigs, and 500 mg./kg. (i.e., 25 mg./kg. D.D.T.) for rats. No skin irritation developed. The animals appeared normal throughout the experimental period, and when killed showed no pathological changes in their organs. Two rabbits, 2 guinea-pigs, and 2 rats received similar treatment, the powder being wetted on application to the skin. No ill effects developed.

3. Impregnated Cloth

Lint was impregnated with 0.5% D.D.T. in benzene and allowed to dry. Portions of this lint containing known amounts of D.D.T. were placed in contact with the shaved skin of rabbits and kept there for 7 days by means of strapping. Five rabbits were so exposed to a dose of 100 mg./kg. D.D.T., five to 50 mg./kg., five to 25 mg./kg., and five to 10 mg./kg. The skin at the site of application of impregnated lint remained healthy. No symptoms of D.D.T. intoxication developed and no pathological changes were found in the organs when the animals were killed at the end of the 7 days.

Repeated Oral Administration of D.D.T.

Ten rabbits and 10 rats were given daily doses of 50 mg./kg. D.D.T. by stomach tube in the form of a 5% suspension in liquid paraffin and tragacanth. Symptoms of D.D.T. intoxication appeared in 8 rabbits, one showing marked tremors after 4 doses (total of 200 mg./kg. D.D.T.), one after 5 doses (total of 250 mg./kg.), two after 9 doses (total of 450 mg./kg.), one after 13 doses (total of 650 mg./kg.), and three after 16 doses (total of 800 mg./kg.). Four animals died after 8, 10, 11, and 20 doses respectively. The remaining 6 rabbits were killed when they had each received 20 doses—i.e., a total of 1 g./kg. D.D.T. Microscopical examination of the organs from all of the rabbits showed slight to moderate liver necrosis in 8; most marked in the 4 animals that died. In all cases necrotic areas presented signs of resolution and liver-cell regeneration without any fibrosis. Slight tubular degeneration occurred in the kidneys of these 8 animals, with calcification in one only. Other organs were unaffected. Rats proved much more resistant, for none of the group of 10 died during a period of 30 doses—i.e., they survived a total dosage of 1.5 g./kg. D.D.T. Moderately severe intoxication appeared in 4 rats after the 28th dose (total of 1.4 g./kg. D.D.T.). All were examined microscopically. No pathological changes were found in any of the organs; the animals showing signs of D.D.T. intoxication presented no abnormality, strange to say.

Repeated Exposure to D.D.T. "Mist"

Thick "mists" of D.D.T. were put up in a cubic-metre chamber by spraying, with an air-driven mechanical sprayer, 15 g. of D.D.T. in about 30 c.cm. of acetone. This gave a nominal concentration of about 1:1000 D.D.T. at the start of the experiment. Four rabbits, 5 guinea-pigs, and 10 rats were exposed to this mist for 2 hours on 11 occasions during 14 days. Two rabbits died after 8 and 9 exposures, one guinea-pig after 9 exposures and four after 10 exposures, one rat after 4 exposures, three after 5, two after 6, one after 8, two after 9, and one after 10. All showed clinical evidence of D.D.T. poisoning. Evidently rats and guinea-pigs are more sensitive than rabbits to this form of intoxication. But such exposures are severe and probably well out of proportion to practical affairs. A further experiment was carried out in which 5 rabbits, 5 guinea-pigs, and 5 rats were exposed under similar conditions for 2 hours daily on 6 separate occasions to a mist produced by spraying 5 g. of D.D.T. in 20 c.cm. of acetone. This corresponded to an initial concentration of about 1:3000 D.D.T. No symptoms of intoxication developed and no pathological changes were found in the organs when the animals were killed at the end of the experiment.

Clinical Features and Pathological Changes in D.D.T. Poisoning

With large single doses of D.D.T. administered by any route the first signs of intoxication appear in 12 to 24 hours. The animal is cold to the touch, its fur is ruffled, and diarrhoea may be present. It seems to be nervous and very sensitive to stimuli. Muscular weakness sets in about this time, starting in the muscles of the back and soon involving the hind limbs. Fine and, then coarse tremors develop in these regions, the animal shaking violently for hours on end. Movement becomes restricted, staggering, often spastic. The forelimbs are seldom affected, so that the animal can partly support itself or even drag its immobile hind quarters about. Anorexia leads to a rapid loss of body weight. Death may occur in 24 to 48 hours or be delayed for several days. Respiration fails, but the heart continues to beat until the end and sometimes for a few minutes after breathing ceases. Convulsions are rare. In animals tha recover, nervous and muscular signs may develop and last fo some days, eventually disappearing without apparent after effects. No evidence of permanent damage has been seen in such cases.

Pathological examination of acute fatalities reveals little change in the organs. Pulmonary oedema is frequent, and a terminal manifestation. Mild or moderate damage of the live and kidneys, similar to that found after repeated administration of D.D.T., may be present, but is not constant. Occasionally the heart muscle contains more fat in its fibres than is normally the case, and the adrenals may be haemorrhagic. A careful examination of the central nervous system has failed to convince us of specific disturbances, even in the most severely affected animals. Degeneration (chromatolysis, vacuolation, pyknosis) and sometimes destruction of a few anterior horn cells in the thoracic and lumbar regions of the spinal cord have been noted, but are not pronounced. The axons of the cord appear unaffected and the higher levels of the brain and brain stem show no changes. Prolonged search of many sections stained by special histological methods has proved of no assistance in locating the seat of nervous disturbance.

With repeated administration of D.D.T. there are loss of body weight, anorexia, and sometimes diarrhoea. When doses are small nervous symptoms do not develop, but with moderate doses tremors and weakness may come and go. Hypersensitiveness to sounds and other stimuli may be striking. Some animals apparently recover from these effects only to die at a later stage; others continue to shake until the end. Death in most instances is quiet, and apparently the result of exhaustion. A different pathological picture is seen, the liver being severely damaged. Numerous areas of focal necrosis or large areas of centrolobular necrosis are uniformly distributed throughout the organ (Fig. 1).

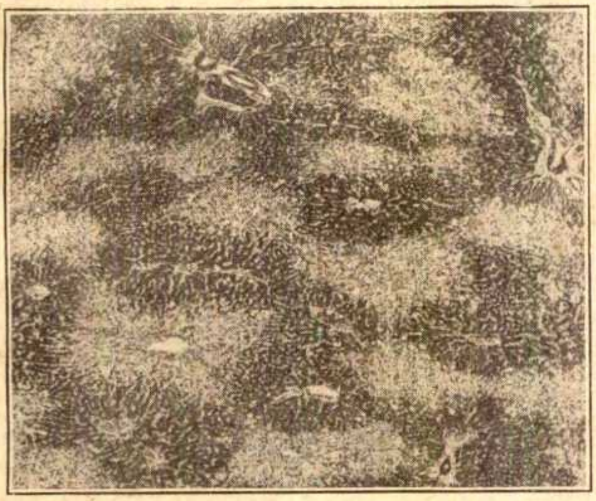

FIG. 1.—Liver of guinea-pig which received daily skin applications of D.D.T.—50 mg./kg. in kerosene—over 9 days. The dark areas are normal liver cells, the pale areas centrolobular necrosis. H. and E. (×30.)

There is much fatty degeneration, with cloudy swelling of liver cells surrounding the necrotic areas. Bile ducts are not affected. Polymorphonuclear leucocytes infiltrate the dead tissue in the early stages; later, mononuclear cells may be numerous. The degree of liver injury is sufficient to account for death. In less severe cases, and especially if D.D.T. be discontinued, necrotic material is removed in the course of a week or two by autolysis and solution as well as by phagocytic activity. Repair is complete, no fibrosis developing even when exposure to D.D.T. is prolonged. Calcification is sometimes seen in some of the necrotic areas. The kidneys, too, are affected, but renal damage is slight compared with that in the liver. Tubule cells show degenerative changes, including fatty deposition and calcification (Fig. 2); sometimes portions of the tubules are necrotic, but glomeruli escape, being congested at the most. The guinea-pig is especially susceptible to calcification. Casts appear in the collecting ducts and Henle loops, but are not numerous. The heart often undergoes mild or moderate fatty degeneration of its muscle fibres, and small focal areas of necrosis have been seen, sometimes infiltrated with polymorphonuclear leucocytes and occasionally undergoing calcification (Fig. 3). Similar necrotic and infiltrated areas have been rarely met with in voluntary muscles. Apart from the more or less rare occurrence of adrenal cortical haemorrhage, the other organs are not affected. A close study of the thyroid gland has failed to convince us of any significant alteration in its structure, but hydropic degeneration and destruction of some of the "water-clear" cells of the parathyroid have been detected during the early stages.

Repeated skin application of D.D.T. in kerosene or in some emulsions may lead to acute inflammation with destruction of the epidermis in places, much oedema of the subcutaneous tissues, and sometimes haemorrhage. Repair follows rapidly when D.D.T. is discontinued. Changes in the blood picture are induced by a large skin application of D.D.T., but are slight with repeated small doses. The haemoglobin percentage tends to decrease, but the red cell count remains unchanged when rabbits are given a large skin exposure. These findings indicate a mild secondary anaemia toxic in origin. Abnormal red cells are not found in the blood. Leucocytosis is also pronounced, starting on the second or third day after exposure usually, neutrophilic cells being mainly concerned. We have noted that animals showing such a response are those which give clinical features of D.D.T. intoxication. In other words, leucocytosis is an intimation that the toxic level is being reached. For that reason it is a useful warning of approaching danger. No characteristic features have been found in the bone marrow of such animals beyond signs of increased white cell production.

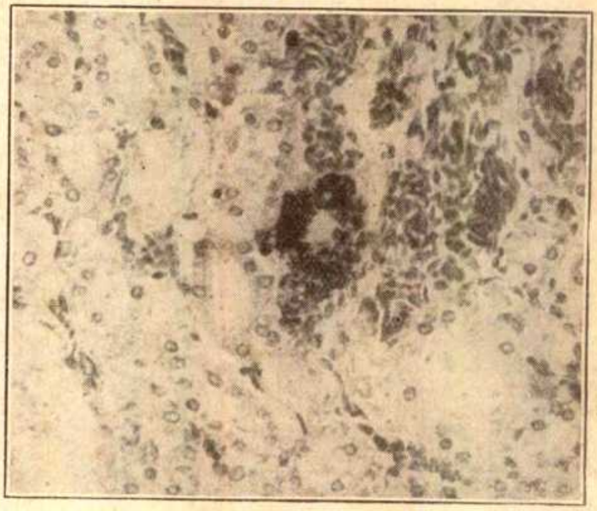

FIG. 2.—Kidney of guinea-pig treated as Fig. 1. The dark annular mass at the centre of the field is a necrotic tubule which has calcified. Near by are necrotic tubules infiltrated with leucocytes and mononuclear cells. v. Kossa and neutral red. (× 350.)

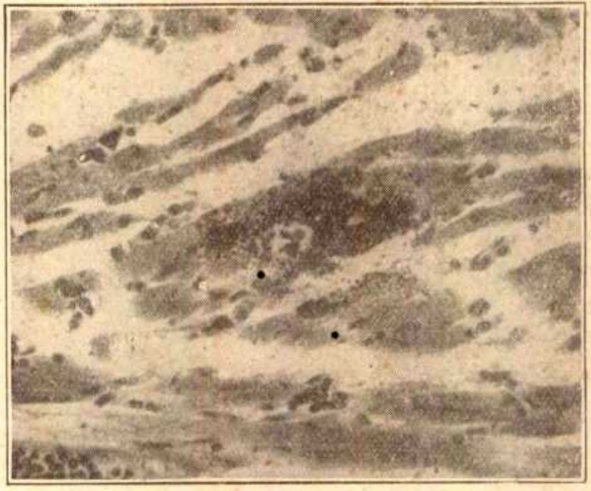

FIG. 3.—Heart muscle of guinea-pig treated as Fig. 1. The dark mass at the centre of the field is a necrotic area of muscle which has calcified. v. Kossa and neutral red. (× 350.)

In rabbits exposed to large skin doses of D.D.T. we have obtained evidence of a rise in blood calcium values. Of seven rabbits investigated for 2 to 12 days after skin application of 200 mg./kg. D.D.T. as a 10% kerosene solution, all showed increase in blood calcium during the first 2 or 3 days, followed by a transient fall below normal levels in most cases. Animals with nervous disturbances showed the most striking changes in blood calcium, although the calcium increased in some animals which were free from nervous signs. We have also obtained similar, though not so pronounced, results in several rabbits of a group of 5 given repeated small skin applications of D.D.T. The increased blood calcium values did not persist, however.

Effect of a Single D.D.T. Contamination on the Healing of Skin Wounds

It is of interest to know whether D.D.T. contamination might influence the healing of wounds, since this possibility might arise in soldiers wearing garments impregnated with D.D.T. We have employed the method described by Young, Fisher, and Young (1941) for the study of healing of experimental wounds. Thirty unselected male rabbits, average weight 2 kg., were given standard circular skin wounds, 1 cm. diameter, on their shaved backs. Immediately after operation the animals were segregated into three groups of 10. Group 1 served as a control, the standard wounds being untreated apart from applying dry dressings. Group 2 rabbits had their wounds sprinkled with 10 mg. of D.D.T. powder immediately after operation: a sterile spatula was used to distribute the D.D.T., which covered the wound almost completely. Group 3 constituted a further control, 10 mg. kaolin being spread over the wound surface. This experiment was an attempt to control the physical property of a powder which must come into consideration when dry D.D.T. is used; it turned out to be a failure, because the kaolin apparently exerted effects on the healing of the wounds. Sepsis was not seen in any animal, and healing went on uninterruptedly. On the third day after operation tracings of the wound outlines were made on "cellophane," and the surface area was estimated in square millimetres. This was repeated at intervals until healing was complete as judged by epithelization of the wound surface and separation of any scab. The mean daily rate of healing was estimated for the period between the third day and completion of healing. Results are summarized in the table together with the statistical constants.

Table showing Mean Daily Rate of Wound Closure in Rabbits

	Number of Rabbits (n)	Mean Daily Rate of Wound Closure (sq. mm. per day)	Standard Deviation (σ)	Standard Error of Mean $\left(\frac{\sigma}{\sqrt{n}}\right)$
Control group ..	10	7·56	2·30	0·77
D.D.T. group ..	7	8·31	1·74	0·70
Kaolin group ..	9	5·02	0·66	0·23

Three of the rabbits of the D.D.T. group and one of the kaolin group died from a pasteurella infection which is not uncommon in our stock.

It can be shown that there is no significant difference between the mean daily rate of closure of wounds in the control (untreated) group and the D.D.T. group. Wounds given one application of D.D.T. powder immediately after their production heal at the same rate as uncontaminated wounds.

OBSERVATIONS ON HUMAN SUBJECTS

Observations were made on human subjects, (1) wearing undergarments impregnated with D.D.T., or (2) working in contact with D.D.T. The first group comprised 52 soldiers, the second 6 workers who were in daily contact with D.D.T. under laboratory or workshop conditions. These trials were carried out in the late autumn and early winter of 1943.

Trials with Impregnated Undergarments

(i) Twelve soldiers volunteered to wear woollen vests, long woollen drawers, and angola shirts impregnated with 1% D.D.T. (dry weight basis). Each man was examined before the trial began and at frequent intervals thereafter; examination included a careful inquiry into past and family history, the present state of health, and physical examination with full investigation of the blood picture and urine. The two latter were repeated at least once, either completely or in part. The men carried out partial military duties during the period of the trial, and on numerous occasions underwent severe exercise to induce copious sweating. The garments were worn throughout the day and night for 18 to 26 days. No symptoms of absorption of D.D.T. developed and the blood and urine remained unaltered. No loss of weight occurred. Two men showed slight dermatitis of the axillary and calf regions, but in both cases, despite the impregnated clothing being worn continuously, this disappeared within 3 days when treated with calamine cream. It does not seem likely that D.D.T. was responsible for the skin irritation, especially as one subject volunteered the information that he was susceptible to skin rashes associated with new clothing.

(ii) Forty volunteers were divided into two groups of 20 each. Group 1 wore vests, drawers, and shirts impregnated with 1% D.D.T. (dry weight basis) for 26 days without changing these garments. In no case were there features attributable to absorption of D.D.T., and physical examination at the end of the trial proved negative. One man developed a slight skin rash on the 10th and 23rd days shortly after taking a bath, but it faded rapidly and could scarcely be connected with D.D.T. Another man showed small spots on his arms on the 18th day, but these disappeared in a day or two. A third had slight acne, which was not made worse by wearing the impregnated garments. It was not possible to examine the blood or urine in this group. Group 2 had weekly changes of underclothes (prepared as in the previous groups), so that each man wore four separate lots of freshly impregnated garments, each set for a week at a time. Some of these men did not wear drawers. One man developed a small papular rash on his forearms on the 18th day, but this disappeared by the 21st day. Another man had some acne for a short period. A third showed slight dermatitis of the wrists, but this likewise cleared up rapidly after application of calamine cream. No subject experienced any ill effects suggestive of D.D.T. absorption. On the last day of the trial all seemed perfectly fit. The blood and urine were not investigated.

Contact with D.D.T. in the Laboratory and Workshop

Six male workers in the Chemistry Section, Porton, were kept under observation during a period of 77 days, in which they were more or less actively engaged in work concerned with D.D.T. The work was classified as (1) laboratory scale, (2) bulk impregnation scale. The latter included such duties as making up large volumes of D.D.T. solution, impregnation of clothing, distillation of residues. Protective clothing, gloves, and gum-boots were worn. Contact through spilling occurred at times. There was also exposure to carbon tetrachloride. Two men had fairly severe exposure in the course of bulk impregnation of garments over 14 and 15 days. One, though having no abnormal symptoms and appearing fit, showed a rise in blood calcium from 11.2 mg. per 100 c.cm. before contact to 18 mg. per 100 c.cm. on the 15th day, falling to 13.4 mg. two days after he left off working with D.D.T. The other man remained perfectly well during his exposure period. The four cases with less severe exposures presented no abnormal features. In no instance was there evidence of skin irritation.

These human trials on 52 soldiers wearing undergarments impregnated with D.D.T., and the laboratory and workshop observations, suggest there is little risk of local skin irritation and general systemic effects attributable to D.D.T., even with prolonged exposure. In many of these experiments there were ideal conditions for absorption from hot sweaty skin.

Discussion

Our investigation shows that acute exposure to D.D.T., applied to the skin, injected subcutaneously, or administered by stomach tube, is tolerated in large amounts by a variety of animals. Repeated administration of much smaller doses is also possible, though there is some evidence that cumulative effects may occur. It is nevertheless true that D.D.T. can exert toxic effects. These are characterized by striking nervous signs, especially muscular weakness, incoordination, and widespread fine and coarse tremors, when the lethal level is approached; and severe damage to the liver, which presents evidence of cell necrosis and functional impairment, when much smaller amounts of D.D.T. are repeatedly absorbed into the system. For that reason it is essential to have some idea of toxic levels of the agent, and the factors which may promote its entry into the body. Although it is not known what is the fatal dose of D.D.T. for men, it can be assumed that this lies somewhere within the range of lethality for experimental animals, hence the importance of collecting such toxicological data. Already there exists much information on this subject, which we summarize below, and to which our own experiments contribute. The ultimate decision whether D.D.T. may be safely employed as an insecticide must depend on how and in what amounts it is used, the precautions taken against accidents, and the elimination of conditions which may assist in the absorption of the compound. Each of these factors is corollary to the other, and no one can be neglected.

Careful studies of D.D.T. have been made by several groups of American workers, with whose results we are substantially in agreement. Woodard, Nelson, and Calvery (1944), using mice, rats, guinea-pigs, rabbits, and chickens, conclude that for oral administration of D.D.T. dissolved in corn oil the L.D.50s are as follows: mouse, 448 mg./kg.; rat, 180 mg./kg.; guinea-pig, > 562 mg./kg.; rabbit, > 400 mg./kg.; chicken, > 300 mg./kg. They stress the fact that its action may be irregular, owing perhaps to irregularities in absorption. Toxic doses were higher for intramuscular, intraperitoneal, and subcutaneous injection. The solvent, too, is important, for toxic doses were higher when D.D.T. was suspended in gum acacia. Toxic effects were more readily obtained with solutions than with suspensions. Diets containing D.D.T. were fed to rats, mice, guinea-pigs, and chickens for 3 days to 20 weeks. Ill effects appeared in rats and mice when the food contained D.D.T. to the extent of 500 parts per million, in guinea-pigs with 1,000 p.p.m., and in growing chicks with less than 500 p.p.m. A wide variation in individual susceptibility was noted. Clinical features and pathological changes were similar to those we have described above.

Draize, Nelson, and Calvery (1944) also studied the effect of the application of D.D.T. to the skin. Powders containing 5% D.D.T. produced no evidence of systemic disturbance or irritation of the skin in rabbits, even when a total amount of 4 g./kg. was applied. In similar acute experiments a 10% solution of D.D.T. in corn oil was applied at dosage levels of 390, 600, and 940 mg. of D.D.T./kg. Apart from slight skin erythema, which persisted about 2 days, no ill effects were experienced. In further experiments rabbit skin-doses amounted to 1.17, 1.8, and 2.82 g. of D.D.T./kg. in dimethyl phthalate and to 0.975, 1.5, and 2.35 g. D.D.T./kg. in dibutyl phthalate. No deaths occurred at any of these dosage levels, although all animals showed symptoms of intoxication, which were very severe at the highest levels. The material, it is true, was poorly absorbed, for approximately 25% of the largest doses could be accounted for on the skin dressings. Subacute experiments were also carried out; 0.5 c.cm. of a 5% suspension of D.D.T. in diethylene glycol monoethyl ether was applied daily for 3 weeks to a 2.5 sq. cm. area of the back of each of 6 albino rabbits. A mild erythema developed during the second week of application, but apparently no toxic symptoms. Ninety-day experiments on rats, guinea-pigs, rabbits, and dogs were performed, using a 30% solution of D.D.T. in dimethyl phthalate. The rabbits, rats, and guinea-pigs were inuncted at dosage levels of 150, 300, 600, and 1,200 mg./kg., the dogs at levels of 300, 600, and 1,200 mg. D.D.T./kg. None of the dogs showed any symptoms of toxicity. Careful microscopical examination of their organs disclosed little change apart from slight to moderate degenerative changes in the livers and some monocellular infiltration of the gall-bladder. We find it difficult to attach much importance to these histological findings. Rabbits, rats, and guinea-pigs appeared equally susceptible to such inunctions. Wide individual variations were encountered. The authors state that inunction of doses as low as 0.5 ml. of a 30% solution of D.D.T. per kg. per day (150 mg. per kg. per day of D.D.T.) may cause death in some cases after 30 days. Some animals survived 6 to [illegible] doses of 600 and 1,200 mg. D.D.T./kg. We would point out that when these doses are expressed in total amounts of D.D.T. administered the amounts tolerated are impressive, even in the experiment in which 150 mg./kg. was applied for 30 days. Obviously the solvent is highly important in such tests, for in our own tests, with different solvents, we observed deaths after the application of much smaller total amounts of D.D.T. It is a matter of great importance, therefore, to make sure that the solvent does not encourage absorption of the insecticide.

Draize *et al.* report that patch tests in human beings and the daily contact of hands of operators with 30% solution of D.D.T. in dimethyl phthalate produced no evidence of irritation. They also describe moderate leucocytosis in animals and successful attempts to sensitize guinea-pigs to D.D.T. The pathological investigations connected with these experiments are separately described by Nelson *et al.* (1944). The main macroscopic features were scaliness or hyperkeratosis of the skin, a pale liver or one showing darkened centrolobular areas, occasionally slight pitting of the kidneys, pulmonary infection in a few animals, chiefly guinea-pigs, occasionally focal haemorrhages in the gastric mucosa, jaundice in one dog, and slight or moderate atrophy of muscles and viscera due to lessened food intake. The surface of two rabbits' gall-bladders was mottled, with oedema of the wall in one. Microscopical findings fell into two groups: (1) those found regularly, and (2) inconsistent changes. Among the former are included moderately severe liver damage in all species except chicks ("little or no liver damage"); focal necrosis of small segments of voluntary muscle, especially with higher doses; hyperkeratosis of skin; and, in rabbits, slight focal epidermic necrosis. Colloid depletion and epithelial desquamation in the thyroid seemed to be common in dogs, rabbits, and guinea-pigs, but not in mice (only two examined). Inconsistent changes include an increased incidence of "spontaneous" encephalitis and focal nephritis of rabbits, gastric mucosal haemorrhages and necrosis, myocardial necroses, haemolytic pigmentation in the gastro-intestinal tract, bone-marrow hyperplasia, and inanition testicular atrophy. The central nervous system was thoroughly searched for lesions, but with negative results. Some information about the response of large animals to D.D.T. are included in this paper. Three cows, three sheep, and one horse received 100 to 200 mg./kg./day of D.D.T. for 3 weeks (one week for one cow and one sheep), either mixed with the food or in capsules when the appetite fell off, as usually happened. Two of the cows developed slow tremors or shaking, especially in the hind legs and neck; none of the other animals of this group developed tremors. None died. Slight fatty degeneration of the liver was found in one cow, and very slight focal necrosis of this organ in another cow. One sheep had slight central necrosis of the liver. Other lesions included atrophy of the spleen, probably inanitional, terminal subendocardial haemorrhages, and very slight focal necrosis of voluntary muscles. No other lesions attributable to D.D.T. were found. It will be seen that the significant changes described by these authors closely agree with those we have observed, with the exception of thyroid alteration, which did not impress us.

In a study of the pharmacological action of D.D.T., Smith and Stohlman (1944) give data for toxicity to animals. They assess the L.D.50 for rats and rabbits given D.D.T. in 1 to 5% solution in olive oil by stomach as 150 and 300 mg./kg. respectively. Two cats receiving 100 and 200 mg./kg. survived. Another cat died after 200 mg./kg. Of eight cats receiving 300 mg./kg. 62% died.

Symptoms were typical and similar to those described by other observers. Cats showed persistent extensor opisthotonos with fine and coarse muscular twitchings, especially of the muscles of the head and neck, lasting for several days, after single oral doses of 300 mg./kg. Rats fed 1,000 parts per million in a semisynthetic adequate diet containing 18% casein died in from 18 to 80 days, but survived 3 months' feeding with 500 p.p.m. D.D.T., though showing tremors and hyperexcitability. In rabbits daily oral administration of 50 mg./kg. D.D.T. in olive oil resulted in death in from 15 to 23 days after a total dose of 0.75 to 1.25 g. per kg. had been given. Parenchymatous liver degeneration with centrolobular necrosis was the most pronounced finding in these. Mild anaemia developed, but white cell counts were not abnormal. Two cats receiving 50 mg./kg. every day or every second or third day developed the characteristic features of poisoning and died—one within 12 days after a total dose of 500 mg./kg., the other within 15 days after a total dose of 300 mg./kg. A third cat, which received 4 doses of 90 mg./kg. within 10 days, died with typical tremors, ataxia, spasticity, paralysis, and terminal extensor rigidity. Skin absorption occurred when 5% solution of D.D.T. in dimethyl phthalate was applied daily over 12 to 14 days in amounts equivalent to 100 mg./kg. D.D.T. The addition of 10% cyclohexanone to such solution did not increase toxicity. Smith describes a useful method for the estimation of D.D.T. in the tissues, body fluids, and excreta, and gives valuable figures for the organ contents. D.D.T. was found in the urine, blood, liver, kidneys, and central nervous system in experimental poisoning.

Lillie and Smith (1944) report on the pathological findings in the animals studied by Smith and Stohlman. The spinal cord of one cat displayed partial tigrolysis of anterior horn cells with pericellular vacuolation; in another cat Nissl bodies were absent from these cells and pericellular and paranuclear vacuolation present. The liver of cats showed fine fatty degeneration, increasing with longer periods of ingestion of D.D.T. A single focus of coagulation necrosis was found in the liver of one cat. The spleen and kidneys showed no definite changes. Focal haemorrhages occurred in the lungs of one cat, congestion and serous exudation in another. Rats receiving daily doses by stomach equivalent to two-thirds of the lethal dose showed some myelosis and haemosiderosis of the spleen, cloudy swelling, fine fatty degeneration and hyaline casts in some kidneys, hydropic central fatty degeneration, congestion, atrophy, and isolated necrotic cells with some fibroblastic proliferation in the liver. Partly organizing foci of coagulation necrosis were found in this organ in two animals. The brain of rats, killed 3½ to 5½ hours after large doses orally, presented vacuolation of some nerve cells, tigrolysis, and basophilic reticulation of cytoplasm of cells in tegmentum pontis only. Feeding D.D.T. produced fatty and hyaline change in the liver and inconstant fatty change in the proximal convoluted tubules of the kidneys. Rabbits killed in less than five days showed moderate to finely marked centrolobular fat in the liver, splenic haemosiderosis, and occasionally fatty change in the kidneys. Liver lesions were more severe, including centrolobular degeneration and necrosis, in rabbits repeatedly fed on olive-oil suspensions of D.D.T. (50 mg./kg./day total amounts, 0.9 to 1.3 g./kg./day D.D.T.). The brain and spinal cord showed vacuolation around large neurones. The remaining organs were not affected or showed very slight inconstant changes.

Hazards from the use of aerosols, mists, and dusting powders containing D.D.T. have been investigated by Neal *et al.* (1944). Dogs, rats, and guinea-pigs exposed to initial concentrations of 54.4, 12.44, and 6.22 mg./litre D.D.T. in air for 45 minutes under static conditions apparently develop no toxic signs or symptoms. Mice tolerate 6.22 mg./litre if the aerosol contains only 6% sesame oil, but if the concentration of the latter be increased to 9.5% toxic features are seen. Higher concentrations than 6.22 mg./litre cause symptoms and death in a few hours, with pathological changes in liver, kidney, spleen, and spinal cord. The chronic toxicity of aerosols was also carefully investigated. Two puppies were exposed for 45 minutes to a concentration of 12.2 mg. D.D.T./litre, using 1% D.D.T., 6% sesame oil, and 93% freon, on 2 successive days in one week and on 4 successive days in the following week. They showed no signs of intoxication and gained weight. Their organs were unaffected. Ten mice, covered with gauze to prevent fur contamination and exposed in the same way, showed no toxic symptoms, but one died from an unknown cause 3 days after the last exposure. Ten unprotected mice died with typical symptoms of D.D.T. poisoning. Ten mice protected against ingestion showed slightly delayed and somewhat less severe symptoms than unprotected animals, the majority dying 5 days after exposure. Pathological changes in mice included enlargement and fatty change of liver cells with variable congestion, fatty change in proximal and distal convoluted tubules with occasional hyaline casts and congested glomeruli, haemosiderosis of spleen, chromatolysis, occasionally vacuolation, and karyolysis of many of the anterior motor neurones at various levels of the spinal cord. Daily exposure of 2 monkeys and 10 mice for 45 minutes, 5 days a week, over 5 weeks, to intermittent concentrations of 0.183 mg. D.D.T./litre in air—prepared by dispersion every 15 minutes of 1.5 g. aerosol containing 5% D.D.T., 10% cyclohexanone, and 85% freon—caused no toxic effects. If repeated 3 times daily for 4 weeks mice were affected, but monkeys showed no signs of intoxication. The organs of the monkeys were normal; the mice presented rather indefinite liver changes, some nuclei showing various stages of karyolysis. Two human subjects were kept for 1 hour daily on 6 consecutive days in a sealed chamber, 14,750 litres capacity, in which was dispersed every 15 minutes 10.40 g. aerosol containing 5% D.D.T., 10% cyclohexanone, and 85% freon. Neither showed symptoms. Exposure to 10.40 g. of a similar aerosol dispersed every 5 minutes for one hour daily on 5 consecutive days was likewise without ill effects apart from some irritation of the eyes and upper respiratory tract. Higher concentrations of D.D.T. in air cannot be built up by repeated dispersion of an aerosol, as the D.D.T. settles out so rapidly and sticks firmly to any surface. In other words, the maximal aerosol concentration is tolerated by man. Daily exposure for 3 hours, over 4 weeks, to concentrations of 12.48 mg./cubic metre of pure D.D.T. in air, using 10% D.D.T. pyrax dust, produced no toxic effects in dogs. One dog presented microscopical evidence of healing acute liver necrosis. Mice exposed in the same way to 13.9 mg./cubic metre pure D.D.T. experienced intoxication, possibly due t licking dust from their fur. Daily insufflation of 100 mg./k pure D.D.T. 6 days a week for 7 weeks caused toxic symptom and damage of liver, kidneys, and nervous system in one of dogs after 18 days. A fourth dog receiving 100 mg./kg. for weeks and thereafter 200 mg./kg. in 8 fractions for 5 weeks di not show any definite symptoms, though it lost weight an vomited once. Daily oral administration over 7 weeks o 100 mg./kg. pure D.D.T. in 4 fractional doses caused no toxi manifestations in dogs. Rabbits exposed for 48 minutes dail over 4 weeks to a heavy mist of 1% D.D.T. deobase mixtur showed some irritation of the mucous membranes of the eye upper respiratory tract, and skin, but no evidence of poisonin

Neal *et al.* conclude that the use of D.D.T. in 1 to 5% solutio in 10% cyclohexanone with 90 or 85% freon as aerosols shoul offer no serious health hazards when used under condition required for insecticidal purposes. Powders of D.D.T. containing concentrations up to 10% also present no serious risk owing to the relative insolubility of D.D.T. and the large particulate size of the dust. Sprays of 1% D.D.T. deobase mixtur should be safe. Ingestion of massive doses of D.D.T., howeve is dangerous.

Conclusion

It is apparent from this summary of American investigation and the results of our own experiments that animal tests, thoug indicating the toxic features of D.D.T., make it clear there is wide margin of safety in its use as an insecticide. We ha always maintained that, provided a maximum concentration 0.5% D.D.T. be insisted upon for sprays, there is no reason anticipate any danger to man. Only gross carelessness wou be likely to lead to serious features. Even with long-continue exposure to such sprays it is difficult to see how ill effects wou be incurred. On the other hand, we are convinced that me handling higher concentrations should take precautions again skin contamination. Cleanliness is essential, the use of glov and protective garments advisable. In spraying concentrat the use of respirators is advocated. We are in agreement wi other workers that dry powders of D.D.T. present no danger absorption from the skin. It is only when oily solvents a employed that such risks are likely to arise; and here aga there is much variation according to the type of solvent use Moreover, it is our experience that ample warning of t approach to toxic levels is given in the form of anorexi muscular weakness, and fine tremors. If at this stage D.D.T. discontinued complete recovery is the rule in animals. Ev when liver damage has developed, a fatal issue is not necessari inevitable, for the organ may still retain its capacity regenerate if further D.D.T. absorption be prevented. Difficul arises when liver degeneration sets in without premonito symptoms or associated nervous signs and a fatal degree hepatic insufficiency may be reached without warning. We ha learned to attach importance to rapid decrease in body weig in such instances. Other features of value in assessing tox absorption are the development of anaemia and leucocytos A rise in blood calcium may also be suggestive, though it is t inconstant to be of any great diagnostic value.

Animal investigations of a new compound have their val and must of necessity be the first approach in the assessment toxicity risks, but they can never completely replace observatio on man. Such limited data as we have been able to colle together with the few American tests on human subjects, indica that under practical conditions there is little reason to exp danger to health. Increasing experience of the handling D.D.T. in factories, in the field, and in Army services seems bear out these conclusions. Nevertheless, it must be emphasiz that there are risks when carelessness leads to the contaminati of body surfaces with concentrated oily solutions of D.D.T.

Summary

An experimental investigation of the toxicology of D.D.T. on variety of animals is described, together with observations on hum subjects exposed for some time to this compound.

D.D.T. is tolerated in fairly large amounts when administered single or repeated doses. Toxic levels are not easily reached wh dilute solutions suitable for insecticidal purposes are employ Danger to health is likely to arise only from careless use concentrates.

Prolonged contact with undergarments impregnated with D.D.T. has not produced any local or general disturbance in human subjects.

D.D.T. poisoning is characterized by nervous symptoms and the development of severe damage to the liver. Premonitory symptoms and changes in the blood picture give warning of the onset of the toxic stage.

We are indebted to the Director-General, Scientific Research and Development, Ministry of Supply, for permission to publish this investigation, and to the commandant and officers of the Army School of Hygiene and to Lieut.-Col. H. Cullumbine, R.A.M.C., for assistance in the human trials. Much help was given in laboratory experiments by Messrs. J. W. Allen and S. P. Rutland. We wish to thank Dr. F. F. West, chief chemist to Messrs. Stafford Allen and Sons Ltd., London, and Messrs. Geigy for supplies of D.D.T.

ACUTE POISONING DUE TO PETROL VAPOUR

BY

J. STEWART LAWRENCE, M.D., M.R.C.P.
Physician to a Hertfordshire Emergency Hospital

On July 3, 1942, it became necessary, for security reasons, to place a charge of explosive in the vicinity of a large storage-tank used for aviation spirit. A boring had been made alongside the tank a month previously, the last 12 feet being completed on the day of the accident. Into it a workman descended, and as petrol had been leaking from the tank into the boring he wore an oxygen-breathing apparatus. This had been carefully tested beforehand and found to fit accurately. About 10 minutes after e had descended those above saw that he was behaving oddly. He was standing at the bottom of the boring, holding on to a ross-bar and reeling drunkenly. His mate, who was near by, was immediately informed, and, though unprotected from the fumes, he promptly climbed down in the pit to render assistance. Arrived at the bottom, he could see that petrol was floating on some water there, and the air was filled with the fumes, so that is eyes smarted. He called for a rope and started to heave his mate, who was heavier than himself, laboriously from one horizontal strut to another up the vertical sides. After the first minute or two he could scarcely breathe owing to a sense of constriction in his chest, and he felt sick and began to retch. Nevertheless e persisted doggedly and had heaved his mate on to the top strut, within reach of the helpers above, when he was overcome y dizziness and fell to the bottom again. The shock of the fall rought him to his senses, and he once more began to climb. He had again reached the top strut, when he completely lost consciousness. This time, fortunately, he was seized from above and pulled to safety.

Case I

When the first workman had been lifted out it was found that he had ceased to breathe, and artificial respiration had to be employed for half an hour before normal breathing could be restored. The patient then became restless and violent and had to be given half a grain of omnopon to keep him quiet during transit to hospital. On admission there, soon after, he was still semiconscious, but sisted attempts at examination. He was cyanosed and his respirations were slow and shallow. The pulse was strong—75 a minute—and there was no fever. He was given continuous oxygen with a B.L.B. mask, and in a few hours had regained consciousness. Next day he complained of discomfort in the right iliac fossa, and examination revealed tenderness in this region. He was now perfectly rational and showed no cyanosis. Examination of the cardiovascular and respiratory systems revealed no abnormal physical signs. The urine contained no albumin or sugar, nor were abnormal amounts of lead detected in urine or faeces. A blood film showed no punctate basophilia.

By the fourth day he felt well, apart from slight residual discomfort and tenderness in the right iliac fossa, which persisted till the 12th day. He was discharged from hospital on the 14th day and remained well subsequently. There had been no sequelae when he was heard of two years later.

Case II

The second workman had also stopped breathing when carried to a place of safety. Spontaneous breathing, however, returned after artificial respiration had been applied for five minutes, and he regained consciousness shortly after. He then complained of a choking sensation and a feeling as of a ball in his chest, and felt that he could not take a deep breath. In the ambulance on the way to hospital he had several attacks of abdominal pain. These had become very severe when he reached hospital and were recurring frequently, being associated with much restlessness and excitement. A third of a grain of morphine failed to give relief, so that evipan was injected slowly into a vein till a quiet sleep was procured. In a few minutes, however, he was again restless, and became so violent that it required four people to hold him down. Further evipan had to be given, and this produced an adequate depth of sleep. Next day the pain had returned, but was less severe, and was readily controlled by morphine. There was also retention of urine, requiring catheterization, and headache was still severe.

On examination he was perfectly rational. His pupils were small but equal and reacted to light. The knee- and ankle-jerks were equal and active, and the plantar responses flexor. There was marked abdominal tenderness and guarding, especially in the epigastric region. Examination of the alimentary system proved otherwise negative, and no abnormal signs were found in the cardiovascular or respiratory system. On flexion of the cervical spine there was complaint of pain in the chest. The temperature, pulse, and respiration rates were unaffected. There was no albumin or sugar in the urine, and no abnormal amounts of lead were detected in urine or faeces. A blood film showed no punctate basophilia. The cerebrospinal fluid was clear and colourless, had a pressure of 150 mm., with protein 36 mg. per 100 c.cm., and no increase of globulin or cells.

Attacks of abdominal pain requiring morphine for relief continued till the fourth day, headache being troublesome up to the third day. A urinary infection then supervened, but this responded rapidly to sulphanilamide. The patient was discharged from hospital on the 18th day, having made a complete recovery. A cough developed soon after discharge and persisted for a year. When seen two years later he was in excellent health.

Factors in Toxicity of Petrol

Originally motor spirit was derived entirely from petroleum by simple distillation. From the crude petroleum the portion distilling up to 150° C., and known as raw benzine or naphtha, was first separated, and from this, by re-distillation, petrol boiling at 50–140° C. and pure benzine boiling at 120–150° C. were obtained. Petrol so produced is known as straight-run petrol, and consists largely of pentane, hexane, and heptane. Petrol is also obtained by "cracking" or splitting up the higher paraffins in the petroleum; it then contains olefines as well. The hydrocarbons in these two types of petrol are subject, when used as a motor spirit, to "knocking," or detonative explosion with air. Petrol containing a high proportion of octane is less prone to this fault. As neither crude nor cracked petroleum yields petrols containing an appreciable amount of octane, this is made by the re-forming of either "cracker" gases or straight-run petrol into branched-chain hydrocarbons such as iso-octane (2 : 2 : 4-trimethylpentane) by processes of catalytic combination. Such processes are used particularly in the production of aero spirit. Unfortunately the toxicity of the aliphatic hydrocarbons increases in proportion to the specific gravity and boiling-point (Tschernikow *et al.*, 1935). N-octane, for example, is seven times as toxic as pentane. It is possible that the iso-octane in aero spirit may not be quite so toxic as n-octane—as dimethyl hexane, for instance, is only three times as toxic as pentane. Petrol produced by "cracking" petroleum has a toxicity similar to that of straight-run petrol (Lazarew, 1929).

Aero spirit was the toxic agent in the cases here described. It has a 10% evaporation point of 75° C., whereas in ordinary winter motor spirit the 10% evaporation point is 52° C. The final boiling-point is 180° C., as compared with 140° C. for motor spirit. Like the latter, it may contain a small percentage of benzene and other aromatic hydrocarbons, and these are of still greater toxicity. Benzene, or benzol, which is normally obtained from coal-tar distillation but is also present in certain petroleums, particularly those from Borneo, Rumania, and Galicia, should not be confused with benzine, which comes solely from petroleum, as already described. As benzine and motor spirit differ but little in composition, the clinical picture in such intoxications is also alike, and the group will therefore be considered as a whole.

Lead tetra-ethyl is not a hazard except to those who produce or blend it or to cleaners of storage-tanks in which evaporation and concentration may have occurred. The amount normally present in petrol is too small to be toxic.

The concentration of petrol vapour required to produce toxic symptoms in man was investigated by Fieldner, Katz, and Kenney (1921) after the death of a rescue worker who entered a petrol tank wearing a half-hour type of oxygen-breathing apparatus. They found that 1 part per 1,000 produced drowsiness at the end of 15 minutes, and vertigo, ataxia, and nausea after one hour, and 7 parts per 1,000 definite intoxication in 5 minutes. In dogs Haggard (1921) found that 10 parts per 1,000 caused convulsions or spasm, 20 parts unconsciousness, and 25 parts death. The effect was similar to that of ether, but the stage of excitement was replaced by convulsions, and the stage of surgical anaesthesia was very brief. Susceptibility is an important factor in toxicity, tolerance resulting from repeated exposure (Machle, 1941).

Circumstances in which Poisoning Occurs

Severe cases of poisoning by inhalation have occurred for the most part in workmen entering benzine tanks or stills to clean or scale them (Foulerton, 1886; Jansen, 1937; Rambousek, 1913), or while emptying such containers (Stiefler, 1928; Petrie, 1908). Coste and Wolz (1935) have recorded two fatal cases due to overflow of petrol filters in a confined space, and Wichern (1909) a case of severe poisoning due to benzine left overnight in the conduit leading from a benzine storage-tank. The victim may become unconscious so rapidly that he is unable to save himself or call for assistance, and may be found dead some hours later. Similarly in excavations or in the pit of a garage (Petrie, 1908; Plummer, 1913), a small amount of petrol may result in dangerous concentrations of vapour, as, being heavier than air, it collects at the bottom.

Mild intoxication is frequent in rubber factories, where it is known as "naphtha jag." While cleaning the rubber churns, for example, workmen may be overcome by the fumes, and in the dipping-room, where they work over large tanks of rubber dissolved in naphtha, severe poisoning may result, as the temperature of the room is kept above 90° F. to aid evaporation. A fatal concentration of the vapour may be found in the drying cupboard in which rubber-leather fabric is hung during its manufacture (Floret, 1927). Kulkow (1926) described mass poisoning when the ventilation system broke down for three-quarters of an hour in a factory making galoshes. In all some 90 persons were affected, 30 requiring transfer to hospital.

The use of petrol in any enclosed space such as a garage may give rise to toxic concentrations. Potts (1915) has described how a man filling automobile tanks fell over unconscious, remaining so for several hours. Permanent damage to the central nervous system, with ocular palsies and pyramidal and cerebellar signs, resulted. Painters working with quick-drying paints in interior decoration may complain of mild symptoms. Lives have been lost from benzine fumes in a carpet-cleaning establishment (Hamilton, 1925).

Leakage or spilling of petrol has been a frequent cause of severe poisoning, as from a bottle of petrol broken in a druggist's cellar (Siemon, 1896), or while cleaning the engine-room of a ship (Johnstone, 1941). Even drawing off benzine into cans in an ill-ventilated room such as a back shop or cellar may result in unconsciousness and death (Floret, 1927). In the home the use of petrol or benzine for cleaning clothes has at times had serious consequences, as when the clothes are soaked in a basin indoors. Petrol has also been used to clean the scalp by pouring it over the hair (Houghton, 1908). This incidentally causes, in addition to general symptoms of intoxication, severe pain and oedema of the scalp. The use in a bedroom of a floor polish containing petrol may result in severe poisoning if ventilation is poor (Roth, 1933).

It is rare for petrol fumes from an internal combustion engine to cause poisoning. Carbon monoxide is a much greater danger. Johnson (1913), however, has described how a number of workmen were affected on several successive days when a petrol engine was used in a tunnel. Carbon monoxide was excluded in this instance. Poisoning from petrol fumes while driving a motor-car is extremely uncommon. Only when the vehicle is manœuvred in a small closed garage while running on a very rich mixture is intoxication likely (Box, 1908).

In wartime petrol may have to be dispatched over-seas in cans stacked in the hold of a ship. If too great a load is put on these the cans in the lower layers may collapse and petrol escape into the hold, thus exposing dock-workers to a high concentration of the vapour. Rudd (1944) has described how in such circumstances men have become unconscious two or three times in one day. Another wartime aspect mentioned by the same author is poisoning due to petrol floating on the sea after the sinking of a tanker. Sailors in lifeboats, intoxicated by the fumes, sprawled over the gunwale and were drowned while sitting in their seats.

Symptomatology

Mild poisoning from petrol or benzine fumes is common in industry, producing symptoms like those of alcoholic intoxication. There is excitement, or euphoria with a tendency to hilarity and, particularly in women, fits of uncontrollable hysterical laughter or crying. Men often become irritable and prone to quarrel. Those who have gained tolerance through repeated exposure may fail to show such emotional changes, and suffer simply from slight tremor of the hands, which makes fine work difficult (Hamilton, 1925; Kulkow, 1926).

From higher concentrations there is in addition irritation of the respiratory mucous membranes, resulting in a dry tickly cough and a sense of constriction in the throat. If exposure is continued the victim becomes ataxic, drowsy, and dull, and may complain of headache, vertigo, nausea, weakness, and irritation of the skin. The vision is blurred, and a burning pain is felt in the chest and abdomen and a feeling of pressure over the heart. In addition there may be tonic contraction of the flexors of the hands and twitching of the muscles of trunk and limbs (Rudd, 1944).

When still greater concentrations are present there is disorientation. The victim shouts abuse at those around and adopts a pugnacious attitude, so that his rescue is fraught with danger both for himself and for rescuers, who may forfeit their lives in the attempt. Hallucinations may be present. If exposure continues, delirium and coma supervene, and there are tonic and clonic convulsions—sometimes in one limb at first, later generalized. Convulsions may not appear till the victim has been removed to the fresh air (Machle, 1941).

If removed to a normal atmosphere the patient may recover quickly if exposure has been short, but later he falls into a deep sleep, from which, however, he can be roused. If exposure has been more prolonged coma may continue for several days and terminate even then in respiratory arrest. As the coma lightens, twitching of the arms and legs may occur, so that the limbs beat against the floor and the teeth chatter violently as though in a rigor. As consciousness returns vomiting sets in, headache is severe, and there is throbbing pain in the abdomen and in the extremities. The patient remains confused for many hours, however, and may relapse into coma from time to time. He is emotionally unstable, and may become pugnacious, throw himself about, or burst into hysterical laughter. When recovery finally ensues it is usually rapid, though vomiting, abdominal pain, and headache may persist for several days and stupefaction and inertia for a week or more.

If the concentration of the vapour is very high the victim falls to the ground unconscious almost immediately, and if not promptly rescued dies of respiratory arrest (Rambousek, 1913).

Physical Signs

Cyanosis is usually present during the stage of coma, and may be deep; the breathing is laboured and stertorous, and the skin cold and clammy. The pulse in the early stages is rapid and weak and may be irregular, but when motor unrest is present it becomes full and bounding. Later, pulse and respirations are slow and feeble and the temperature subnormal. The blood pressure falls as peripheral failure supervenes. Acrocyanosis may be marked. The pupils are dilated and may be unequal, and conjugate deviation, strabismus, or nystagmus is often found. The tendon reflexes are diminished or absent in quiet coma, but when convulsions and motor unrest are present they are often exaggerated, the plantar responses extensor, and clonus present. There may be neck rigidity (Machle, 1941; Plummer, 1913).

The urine sometimes contains traces of albumin and sugar. Unlike benzol, petrol and benzine are not excreted in the urine in conjugation with sulphates (Wichern, 1909). A blood count often shows a moderate reduction of haemoglobin and erythrocytes, and an increase of bilirubin in the serum, but there may be haemoconcentration. A polymorph leucocytosis is frequent and the percentage of eosinophils may be increased. Blood changes are, however, not prominent as in benzol poisoning. Sometimes there is a rise of blood urea, but not sufficient to cause confusion with uraemia. The cerebrospinal fluid is not altered.

Prophylaxis and Treatment

Prophylaxis.—Where petrol is handled in enclosed places adequate ventilation must be assured, so that, when exposure is likely to be prolonged, concentrations of 1 part per 1,000 are not exceeded. Too much faith should not be placed in an oxygen-breathing apparatus, especially when the concentration of petrol vapour is likely to be high, as the fumes have great penetrative power.

Treatment.—The victim should be removed at once to the fresh air. If breathing has ceased, artificial respiration will be required, and oxygen, if available, should be given, preferably with 5% of carbon dioxide. The clothes, as they are saturated with petrol vapour and may be contaminated by the liquid, must be removed and the skin cleansed. Sedatives are required if there is much restlessness, paraldehyde or chloral hydrate generally sufficing. In very violent patients intravenous pentothal may have to be used. A dose of 0.5 g. dissolved in 10 c.cm. of distilled water is injected slowly till a quiet sleep has been procured. The remainder of the dose is then injected intramuscularly to prolong the action of the intravenous dose. Careful supervision must be exercised during the first four days lest respiratory arrest, circulatory failure, or convulsions supervene. In circulatory failure adrenaline should be avoided, as it tends to cause pulmonary oedema (Machle, 1941).

Pathology

The macroscopic changes are found for the most part in the lungs, which are hyperaemic and oedematous and show petechial haemorrhages and extravasations of blood. The bronchi are inflamed. There may also be haemorrhage into the serous cavities and the subserous tissues, and into the mucosa of trachea, gastro-intestinal tract, and bladder. The meninges, brain, and spinal cord are hyperaemic and oedematous, and show petechial haemorrhages. The kidneys are oedematous. Histologically, cloudy swelling and fatty degeneration are found in the liver and in the proximal convoluted tubules of the kidneys. The cerebrum is congested, and there are perivascular extravasations of blood. The nerve cells of the brain and spinal cord show chromatolysis, loss of lipoid, and dendritic degeneration. There is swelling or disappearance of myelin (Jansen, 1937; Machle, 1941).

Sequelae

Mild neurasthenic symptoms, such as headache, sleeplessness, and anorexia, are common after petrol poisoning. Evidence of organic change in the nervous system is, however, not infrequent, particularly epilepsy (Floret, 1927), but also lesions of the pyramidal, cerebellar, or sensory tract simulating disseminated sclerosis or other organic nervous disease (Potts, 1915). The signs may be of scattered lesions or be hemiplegic or of more local distribution. Memory and intellect may be impaired. Sometimes the peripheral nerves are involved, often only a single nerve, such as the sciatic nerve (Jansen, 1937) or one of the cranial nerves, such as the hypoglossal. Retrobulbar neuritis has been recorded. These symptoms and signs may not become evident for several months after the accident, and recovery may take many years, or the disability be permanent. An early and fatal complication, described by Floret (1927) is necrosis of the skin of the face and of the mucous membrane of the mouth and throat, following an erysipelas-like eruption. Pneumonia may occur, but is more common after the inhalation of liquid petrol—as when it is drunk—than of vapour.

Summary

Two cases of acute poisoning due to petrol vapour are described. The aetiology, clinical features, and pathology are reviewed.

I wish to express my thanks to Air Cdre. T. McClurkin and Cmdr. Blake-Smith for technical information.

MONO-ARTICULAR OSTEO-ARTHRITIS OF THE HIP

TREATMENT BY ACID INJECTION

BY

W. GRANT WAUGH, M.D., F.R.C.S.Ed.

During the past nine years I have treated over 1,200 cases of arthritis by intra-articular acid injection, comprising chiefly those of osteo-arthritis, of traumatic arthritis, of so-called "menopausal" arthritis, and of rheumatoid arthritis in the residual deformity stage. Owing to war conditions, effective statistical analysis of results has been impossible; it may, however, be legitimate to gauge the value of the treatment from the increase in the number of patients referred to my two hospital clinics annually—from 56 in 1940 to 186 in 1944. I estimate that over 70% of cases of all types have been rendered free from pain and with sufficient restoration of function to allow of a return to their normal occupation.

Mono-articular arthritis of the hip-joint, however, occupies an unenviable pedestal of intractability among joint affections. According to MacMurray (1943), "local treatment of the affected joint by hot packs, hot mud packs, radiant heat, etc., results in a more or less temporary relief of pain, but produces little interruption in the progress of the disease. Electrical treatment by ionization has proved to be of little or no value, and its use is followed in some instances by a considerable increase in the pain and tenderness." Manipulation has its advocates for early cases; fixation by plaster or other support will give relief from pain; deep *x*-ray therapy is said to effect improvement in about 10% of cases—the Freiburg authorities claimed that 33% of their cases were relieved by deep therapy. As none of these measures has in my experience arrested the disease process and has rarely returned the patient to economic circulation, it seemed that an analysis of the condition of the cases treated by joint acidification in one year might afford some indication of its usefulness or otherwise in this baffling disorder.

The rationale of acidification of arthritic joints is based on my observations on the *p*H of synovial fluid in various conditions (Waugh, 1936, 1938): in chronic osteo-arthritis of the hip this appeared to be consistently on the alkaline side—even as high as 8.8. It has been shown by Smith-Petersen that the use of the vitallium cap after excision of the head of the femur is followed by the generation of a layer of fibrocartilage in the acetabulum and over the stump of the neck: I have not so far been able to obtain a similar specimen from the hip-joint after acidification; but examination of the cartilage removed from the head of the tibia in a case of osteo-arthritis of the knee, which had received a long and successful course of this treatment, showed a covering of fibrocartilage 1/32 in. thick, covering the whole weight-bearing surface.

Warren Crowe (1944) has reported his results in 400 cases of all kinds, using acid potassium phosphate. I prefer lactic acid, as more closely approximating a natural acid found in the tissues: some difficulty was experienced in obtaining a stable preparation of constant *p*H, but this has been overcome.

Technique.—Briefly, the technique consists of (1) an injection each week of 15 to 20 c.cm. of a solution of lactic acid of a *p*H of 5.8, together with procaine, into and around the joint; (2) followed by very gradual manipulation, and flexion-abduction-extension exercises, without weight-bearing, consistently and perseveringly carried out by the patient.

Analysis of Cases

The cases described are of the hospital out-patient class, referred to me either by the physiotherapy department or directly by their own doctor. In all, 142 cases have been examined and 108 treated in this way during the last five years. Owing to removals, bombing, and other causes, I have not been able to attempt a complete follow-up of these cases: I have, however, investigated the result obtained in 26 consecutive cases which were referred to me in the year 1942; and I find that between 50 and 60% of these patients obtain enough relief from pain and recovery of function to be able to carry on their normal occupations, including housework and shop assistant's work in women, and shipyard work—riveting—and even in two instances coal-hewing, in men.

In this condition it is extremely difficult to establish any scientific criterion of success or failure of treatment. Pain, the patient's chief disability, is a subjective matter; with the possible exception of the demonstration of the narrowed joint space, radiography is an indifferent guide to the clinical condition; nor does limitation of range of movement bear any constant mensurable relation to the clinical condition. For a number of years I have made my own percentage assessment of the degree of overall disability. For example, when a patient is for all practical purposes confined to bed he is assessed at from 90 to 100% disabled; others able to get about, but with considerable difficulty, at 70 to 80%. These assessments are entered on the patient's case-sheet at the beginning of treatment, while on completion a final assessment of the degree of disability remaining is made. While this is a purely clinical method of estimation and dependent on the surgeon's personal observation, I find it the most useful means of ascertaining whether the patient has improved under treatment.

Discussion

The chief contraindication to suitability for this form of treatment is extreme loss of joint space, particularly in the outer and upper quadrants of the joint, as seen by radiographs. The amount of osteophytic outgrowth does not in itself, however, govern the suitability of the case for acidification. Extreme loss of joint space indicates extensive destruction of the articular cartilage, and, apart from the unlikelihood of obtaining effective regeneration of joint surface by fibrocartilage, the mechanical difficulty of reaching the space of the joint with the needle is almost insuperable. Five of the 26 cases come into this category, of which two were successfully dealt with by oblique osteotomy; no treatment was given to the remaining three. Three cases failed to continue treatment after the first or second injection, and must be written off. Of the remaining 18 cases, all of which I have examined within the last few months, four were in-patients and carried out what I regard as the complete course. These are naturally the most successful. Three appear to be almost completely free from symptoms: one, a housewife who had been confined to bed or a chair for a year previous to treatment, is now fully active, does all her housework, and can stand in queues and do her shopping. By her own account she is practically free from pain or any disability. There is still some limitation of range of movement, particularly inward rotation. Her original classification was in the 90 to 100% class; I estimate her total disability now as under 10%. The two remaining male cases were those of a coal-miner and a slinger at an ironworks; both are free from pain, but have rather greater limitation of range of movement; they have returned to full work at their heavy occupations. The fourth case is a failure; for a year after finishing treatment this patient continued fairly well, but his condition has since deteriorated. The remaining 14 patients—nine men and five women—were treated purely as out-patients. The average disability figure at the first examination I put down as in the region of 60%; only three (men) are relative failures, in that after completion of treatment the disability figure is still in the region of 40%. The other 11 are all sufficiently recovered to carry on a useful existence, and, in several cases, hard physical work, without complaint of pain; their average remaining disability figure I put at well under 20%. Two of them have returned in recent months, as they felt they were getting more pain. They have been given a further course of six injections; this appears to have cleared up any return of symptoms.

Results in 18 Cases of Mono-articular Osteo-arthritis of the Hip treated by Joint Acidification

	No.	Results		
		Very Good	Good	Poor
In-patients . .	4	3	0	1
Out-patients . .	14	4	7	3

It is not easy to obtain a solution which remains constant; I use that made for me by Brady and Martin, Newcastle-upon-Tyne, which is reliable.

Summary

The method of treatment of osteo-arthritis by intra-articular acid injection is outlined.

Non-operative methods of treatment of mono-articular osteo-arthritis of the hip are itemized.

The results of acid injection in 18 cases are analysed.

TORSION OF A PEDUNCULATED GASTRIC CYST

BY

M. D. SHEPPARD, F.R.C.S.

AND

J. R. GILMOUR, M.R.C.P.

(From Chelmsford and Essex Hospital, Chelmsford)

Cysts of the stomach are rare and few cause symptoms. We describe in detail one case of clinical importance and mention three others in a short discussion upon gastric cysts.

Case Report

Clinical History and Examination.—A woman aged 62 had felt rather full in the abdomen for two years and had noticed a swelling in the right iliac fossa for about four months. She had been troubled with constipation and hiccups also. On palpation of the abdomen a freely movable globular tumour about the size of a grapefruit was found. It was not tender and could be pushed right up under the costal margin. A long-pedicled ovarian cyst was diagnosed and its removal advised.

On laparotomy the tumour proved to be a cyst in the peritoneal cavity with a long pedicle attached to the greater curvature of the stomach. The pedicle was twisted about five times, and the cyst, although not necrotic-looking, was discoloured in places. There were patches of fibrinous exudate and a portion of lightly adherent omentum upon its surface. Muscle fibres of the muscularis of the stomach were observed running from the greater curvature right down the pedicle to the cyst wall. The cyst was removed without difficulty and the patient made an uninterrupted recovery. Subsequent questioning yielded no information indicating when the torsion had occurred.

Pathological Examination.—The specimen consisted of a cyst, 11 by 10 by 7.5 cm., the outer surface of which was greyish blue, smooth, and marked prominently by veins, and a flat layer of adipose omentum was attached over an area 18 by 14 cm. The wall consisted of greyish-white or brown tissue from 1 to 5 mm. thick. The content was a sepia-coloured fluid and clotted blood in about equal amounts. Most of the clot was deposited upon the inner surface of the cyst, and it contained several fragments of grey tissue up to 1 by 0.5 cm. The wall was composed of connective tissue, which in most places was loose and oedematous and in others fibrotic. In a few places in the wall there were bundles of smooth-muscle fibres, but epithelium was everywhere absent. There were foci of lymphocytes, plasma cells, and eosinophil leucocytes, and many patches of recent haemorrhage; evidence of old haemorrhage in places was shown by intracellular or extracellular granular haemosiderin and haematoidin and by impregnation of collagen fibres with ferric and ferrous salts which stained deeply with Ehrlich's haematoxylin. Numerous spindle-shaped areas of proliferated cells and relatively little collagen lay in the wall. The majority of the cells were spindle-shaped, but others appeared to be spheroidal, and in most the cytoplasm was vacuolated or diffusely dropsical. Some of the cells in a few spindles could be identified almost certainly as muscle cells, but the remainder were undifferentiated. In parts of the wall containing bundles of muscle fibres the spindle-shaped thickenings lay in close association with the bundles. No axis cylinders could be seen in the spindles in Bielschowsky preparations. The spindles appeared to result from regeneration of muscle by proliferation of undifferentiated connective-tissue cells, the differentiation into muscle cells being abortive. The haemorrhage in the wall of the cyst was continuous with the deposit of clot upon the inner surface, and the fragments of grey tissue in the clot were spindle areas of cellular proliferation which had become separated off from the wall as the result of haemorrhage.

Discussion

Many gastric cysts in cases reported in the literature were symptomless and were discovered at necropsy. Others gave rise to symptoms which appeared in infancy or at some later age, even in late adult life. Symptoms were variable, but abdominal pain, vomiting, loss of weight, and swelling of the abdomen were the most common. In no reported case was torsion described, but in Tchernisher's case (according to Gray and Wood, 1938) the cyst was attached to the stomach by a long stalk as in our case. Haemorrhage had occurred in the wall of the cyst in the cases of Weichert (1929) and Ladd and Gross (1940), but its cause was not mentioned.

The size and number of cysts occurring in any reported case varied. Three cysts were present in the Cabot case 14242 (1928) and Pancotto's case (1927); and in that of Askanazy (1923) there were numerous cysts. Askanazy described very minute cysts, and Tchernisher (according to Gray and Wood) one the size of an adult head.

According to structure there are four types of gastric cyst. The most common type is the *enterogenous cyst*, which lies in the muscularis mucosae, submucosa, or muscularis in any part of the stomach, but particularly in the pyloric region and commonly at the greater curvature. They probably arise from epithelium separated off from the gastric mucosa during development, but growth of this epithelium into cysts may occur at any time of life. Bikoff (1938) ascribed the origin of a cyst—the size of a hen's egg—which had been removed from the greater curvature to the duct of ectopic pancreatic tissue. It was more likely to be enterogenous, since it was lined with a layer of columnar epithelial cells and a few gland-like structures lay in a subjacent layer of connective tissue. Enterogenous cysts are lined with a single layer of epithelial cells, columnar in most, and they lie upon a layer of connective tissue which in some instances contains a variable number of tubular glands. The formation of well-developed typical gastric mucosa is probably uncommon. A muscularis mucosae is usually present. In the cysts of Wendel (1911), Ferraro (1942), Askanazy, and Pancotto the mucosa was of gastric type, while in the Cabot case the lining mucosa was described as being atrophic gastro-intestinal.

Enterogenous cysts lined with gastric mucosa are not limited to the stomach. Seydl (1938), for example, described such a cyst in the lower posterior mediastinum, and peptic ulceration of the cyst had caused perforation into a bronchus and fatal haemorrhage from an eroded artery.

The following is a description of two enterogenous gastric cysts which, although very small, probably represent the rests from which large cysts of clinical significance arise.

In a female infant of 1 hour, which had absence of the left dome of the diaphragm, diaphragmatic hernia, hypoplasia of the left lung, and coarctation of the aorta, a cyst, 3 mm. in diameter, projected into the greater omentum from the greater curvature at the junction of its middle and upper thirds. It lay in the muscularis and had a muscularis mucosae and a mucosa in which straight tubular glands were very few but like those in the stomach. In the other example a cyst, 3 by 1 mm., was found in the microscopical section of the pyloric region of a part of the stomach removed from a man of 61 because of chronic peptic ulceration. The cyst lay in the muscularis mucosae and was lined with a layer of cubical or short columnar mucous cells.

The second type is a *dermoid cyst*, in which there are two examples only. These cases were inadequately described by Gray and Wood (1938), and no histological data were given.

The third type is that *due to septa*, of which there is only one example. In this case (Metz, Householder, and De Pree, 1942) the cyst was the middle of three compartments of the stomach formed by two complete septa. Gastric mucosa lay on each surface of the septa.

The fourth type is that in which the lining is destroyed, so that the *origin is unknown*. Ladd and Gross described a cyst of this type lined with haemorrhagic necrotic tissue. Our cyst, which had undergone torsion, was of similar type, and the following is a description of another example.

A man aged 68 had had attacks of "the gastric," consisting of belching chiefly, for two years, and abdominal pain, loss of weight, and frequent vomiting for nine days before admission to hospital. A mass was palpable in the right upper quadrant of the abdomen. Death occurred from bronchopneumonia 10 days after admission. The lower two-thirds of the oesophagus had a rough, opaque, bile-stained lining; and microscopically the inner part of the wall was necrosed and undergoing peptic digestion, but the muscularis mucosae was hypertrophied and ghosts of cells probably indicated that inflammation had been present. Mild oesophagitis and cardiospasm probably accounted for the gastric symptoms. A cyst, 8 by 6 cm., lay in the pylorus and had a thin wall of fibrotic connective tissue in which there were few cells in most places and slight lymphocytic infiltration in others. The inner surface was necrosed and undergoing digestion in places. The anterior part lay in the submucosa, but posteriorly the cyst passed through the muscularis into adipose connective tissue to reach the anterior surface of the normal pancreas. The adipose tissue adjacent to the cyst wall showed areas of fat necrosis, which was of pancreatic type in that lipolysis and saponification had occurred. It was evident that the cyst contained ferments which had destroyed the lining epithelium and had caused the fat necrosis. The fact that the latter was of pancreatic type is insufficient evidence for one to ascribe the cyst to ectopic pancreatic tissue in the pylorus.

It is probable that cysts of this type, with absent epithelium, are enterogenous, and that the lining has been destroyed by ferments or circulatory disturbance.

Summary

A case of torsion of a pedunculated intraperitoneal cyst of the stomach, in a woman of 62, is described. The cyst was probably enterogenous, and an epithelial lining had probably been destroyed in consequence of torsion.

The following statement on bread policy has been authorized by the Executive Council of the Food Education Society (29, Gordon Square, W.C.1): (1) The Food Education Society regrets that the Government has reduced the extraction rate of the wheat grain for bread flour to 80% on inadequate scientific and clinical data, especially at a time when the position in regard to food supply in general is so uncertain. (2) There is good reason to think that any reduction below 80% would be detrimental to the health of the people and should not be put into effect without further inquiry and experience. (3) The Society is strongly of the opinion that a specification for the post-war loaf is highly desirable, as in the case of other basic foods.

PATHOLOGY OF RUPTURED PLANTARIS

BY

G. BLUNDELL JONES, F.R.C.S.Eng.&Ed.
Captain, R.A.M.C.

Very little is known of the exact pathology of the lesion described as "ruptured plantaris" because the condition does not require operation and its morbid anatomy is therefore seldom seen. The following case report shows, however, that actual rupture of the belly of the plantaris muscle does occur, and that its clinical features tally exactly with the textbook descriptions of "ruptured plantaris."

Case Report

Sgt. X., aged 31, was admitted to hospital after an accident in which he had been thrown from a motor-cycle while travelling slowly. He complained of severe pain in the left calf region, and was under the impression that he had received a direct blow on the calf. Further questioning showed that he had slid across the road and been brought to a stop by the sole of his left foot hitting the kerb, thus producing forcible dorsiflexion of the ankle.

Examination revealed no evidence of direct injury to the calf, and there was no bruising. He was tender over the whole of the upper third of the leg posteriorly, but acutely so over the site of the plantaris muscle. There was a transverse incised wound over the tendo Achillis 2½ in. long, 3 in. above the ankle-joint. There was no other injury.

The wound was excised under gas-oxygen anaesthesia; the incision involved skin and fascia only, the tendo Achillis being exposed but showing no evidence of damage. On the medial side, a little deeper in the wound, it was noticed that the plantaris tendon was lying slack, and gentle traction upon it resulted in the delivery of the entire tendon and half the muscle belly ruptured transversely about its middle. The lower end of the tendon was detached and the whole removed. The wound was sutured.

Pain in the calf persisted for 2 to 3 weeks and staining of the skin of the leg by effused blood, with some oedema, appeared 3 days after the injury. Dorsiflexion of the ankle beyond a right-angle was painful for 4 weeks and was relieved by raising the heel of the boot. Physical treatment was aided in the early stage by local infiltration with novocain (Campbell, 1938; Smiley, 1939.)

The wound over the tendo Achillis, which allowed the inspection of the plantaris tendon, was presumably incidental, as the deeper structures showed no sign of injury. The plantaris must therefore have been ruptured by indirect violence applied in dorsiflexion of the ankle.

Discussion

The clinical features of "ruptured plantaris" are well known. The average age of 8 cases seen by me was 30, and it is essentially a lesion of relatively young healthy tissues. Classically, a tennis player reaching back for a shot produces a forced dorsiflexion of his ankle; a sudden pain occurs, and he thinks he has been struck on the calf by his partner. Pain increases during the next few hours, and swelling of the leg followed by bruising is seen in 2 to 3 days. A painful acutely tender area over the plantaris muscle belly in the upper third of the calf is present at first, but later pain is felt only when the ankle is dorsiflexed beyond the right angle. The period of recovery lasts about three weeks.

The pathology of the lesion is the subject of much doubt. It is variously supposed to be a subcutaneous rupture of the plantaris tendon, a partial or complete tear of the muscle fibres or the musculo-tendinous junction of the plantaris, or a rupture of some fibres of the soleus or gastrocnemius muscles. The case described shows that, sometimes at least, the symptoms are produced by rupture of the plantaris muscle belly, and the following facts and observations support the view that the clinical syndrome is always so produced.

The plantaris is absent in 7.5% of subjects, according to Gruber, quoted by Quain (1892). Pilcher (1939) found the muscle absent or rudimentary in 16 of 100 consecutive post-mortem examinations, and states that the deficiency is more common in women than in men. The frequency of occurrence of the plantaris muscle is thus compatible with its presence in every case showing the classical clinical picture of rupture.

Greater tension per unit area is developed in the plantaris on forced dorsiflexion of the ankle than in the other calf muscles, because the length of the plantaris belly is only one-fifth of the total length of muscle and tendon; whereas one-half the total length of the soleus and gastrocnemius is composed of muscle fibres. I exposed the tendon in a number of cases for use as a graft in the repair of hernia, after the method described by Pilcher (1939). In each case, when the ankle was fully dorsiflexed the plantaris was seen to be as taut as a bow-string, while the tendo Achillis still showed elasticity. It seems reasonable to postulate, therefore, that in healthy tissues the sequence of events in increasingly violent dorsiflexion of the ankle is: (1) partial tear of the plantaris; (2) complete tear of the plantaris; (3) rupture of the other calf muscles in addition, or the tendo Achillis. Where the tissues are not healthy the order may be altered, as seen in the easy rupture of the tendo Achillis of elderly or syphilitic subjects. The first two of the above possibilities are the lesions occurring with the strain causing the "ruptured plantaris" syndrome.

An attempt was made to rupture the plantaris in a fresh young healthy cadaver by seizing the tendon with a haemostat and pulling. This caused rupture at the point seized, but when local damage was prevented by looping the tendon round a wooden peg, strong traction caused the muscle to tear through the middle of its belly. This, together with the findings in the case described, proves the weakest part of the muscle to be its contractile fibres.

The site of tenderness in 8 cases of "ruptured plantaris" seen by me was over the plantaris muscle belly. This is strong evidence pointing to the muscle itself as the site of the lesion.

Conclusion and Summary

The lesion described as "ruptured plantaris" is in fact a partial or complete tear of the fleshy fibres of the plantaris muscle. The case report correlates the clinical syndrome with a complete rupture of the plantaris muscle belly. The anatomical features of short muscle belly and long tendon cause this muscle to be subjected to greater tension than the other calf muscles—a fact which is well demonstrated by exposure at operation. The weakest part of the muscle is its belly, as proved by the experiment in the cadaver and the findings in the case described. The classical type of trauma causing the lesion in healthy tissues, together with the location of tenderness distinguish plantaris rupture from other similar lesions.

I am indebted to Lieut.-Col. A. F. L. Shields, commanding officer of the hospital in which the case occurred, for permission to publish it.

Medical Memoranda

Cavernous Sinus Thrombosis

There can be no doubt that treatment with penicillin has considerably improved the prognosis of cavernous sinus thrombosis. In a leading article in the *Lancet* (1945) it was pointed out that "chemotherapy is likely to cure just that type of case where the outcome was formerly almost hopeless—spread of infection from anterior veins draining a septic lesion of the face—because a lesion here is plainly visible, and any divergence from routine healing, or signs of more deep-seated mischief become rapidly obvious, so treatment can be begun in time." In addition, treatment with penicillin may result in a cure even when its administration has been delayed for any reason, and Johnstone (1945) has reported a case in which administration was not begun for 10 days, and yet the patient was completely cured.

It may be of interest to record the following case, in which penicillin was not given until 6 days after the onset of the illness, and in which recovery was complete.

Case History

Miss A., aged 23, a ledger clerk, was admitted to hospital on the evening of Jan. 12, 1945, as a case of erysipelas. The illness had begun suddenly on Jan. 8, with headache, limb pains, and vomiting. On the 9th she was put to bed, and since the afternoon of the 11th had been given a total of 6 g. of a sulphonamide. On examination she had an area of erythema extending from the right cheek to the forehead and spreading across the nose. It was extremely tender and slightly raised. Both eyelids were oedematous. Her temperature was 103.2° F., pulse 120. She was immediately given 2 g. of sulphadiazine, followed by 2 g. 4 hours later, then 1 g. 4-hourly, with pot. cit. and plenty of fluids.

On Jan. 13 her condition was much the same, but her eyelids were more swollen—she could not open her right eye at all. The temperature was swinging between 99.2° and 101° F. during the day. At 10 a.m. on the 14th her temperature was 100.2° F. and the eyelids were worse. The right eye was definitely proptosed, and the left slightly so, and both showed early chemosis. She complained of feeling "dopy," was apathetic, and was rather slow in answering questions. A diagnosis of cavernous sinus thrombosis was made. At 2 p.m. the temperature was subnormal, but there were some petechiae on her eyelids and body. Treatment with penicillin was begun with a dosage of 20,000 units 3-hourly, intramuscularly. The sulphadiazine was discontinued. During Jan. 13 and 14 the patient had several rigors.

On Jan. 15 her temperature had risen again, there was marked chemosis of the conjunctivae of both eyes, with a blue discoloration of the eyelids, and she felt extremely drowsy. She complained that when she managed to open her eyelids a little she found that the vision of her right eye was blurred, but her left one was normal. Her pupils were small but reacted to light; and her external ocular movements were grossly restricted. It was impossible to examine the ocular fundi. Her general condition was worse, and a course of sulphathiazole was started—1.5 g. 4-hourly. All day she was extremely drowsy, with a swinging temperature.

On the morning of the 16th the temperature was normal. She still felt very drowsy, but had had 2 gr. of phenobarbitone in the early hours of the morning. Her eyes were painful but definitely less swollen, and the condition appeared much more localized. A boil on the right side of her nose was beginning to point—there had been no evidence of this previously, as the whole cheek had been swollen; hot fomentations were ordered. Her temperature rose again to 101.4° F. that night, and the next morning to 102.2° F. At this time the local condition was very much better and there was less chemosis, but a few fresh petechiae were present on the trunk and she complained of a stiff neck. All meningeal signs were equivocal. Her spleen was not palpable. By that night the temperature had dropped to normal and risen again to 100° F., and she was complaining of very severe pain in the head and neck. During the night there was a discharge of thick green pus from the boil on the nose, from which *Staph. aureus* was subsequently grown. The temperature was down again in the morning and the patient was much better subjectively. The sulphathiazole was reduced to 1 g. 6-hourly.

On Jan. 19, 20, and 21 the temperature was still swinging, but never reached 100° F. The eyes were practically normal. The sulphathiazole was stopped on the 19th, after a total of 34 g. had been given. On the night of the 22nd, the temperature having been normal for 36 hours, the penicillin was stopped after a total dosage of 1,320,000 units. On Jan. 23 the patient complained of double vision, and had a left external rectus paresis. On the 26th this was no better. The optic disks were apparently normal except for slight blurring of the nasal side of each. On Feb. 7 she complained of tenderness in the distribution of the right supra-orbital nerve, which had troubled her for about a week.

The patient was discharged on Feb. 14 feeling perfectly fit but for slight diplopia on looking to the extreme left, and with what she called her "old face again."

Discussion

But for penicillin this patient would almost certainly have died. Although no blood culture was done, the swinging temperature and the occurrence of petechiae and rigors indicated that she had a septicaemia. There may also have been meningeal involvement in view of the severe pain in the head and neck, with equivocal meningeal signs. Lumbar puncture was not carried out, as the pain was well relieved with 1/6 gr. of morphine and did not recur with the same severity; and little more could have been done therapeutically if it had been definitely known that meningitis was present, except perhaps the administration of penicillin intrathecally.

Prof. Garrod (1945) found that sulphathiazole *in vitro* "somewhat reduces the rate of disinfection by penicillin." Does the present case bear this out *in vivo*? Would the patient's condition have improved more rapidly with penicillin alone? The temperature had not come down to below 100° F. permanently until after the sulphathiazole was stopped; 36 hours after that it had become normal for good, and penicillin was discontinued 36 hours later. But probably the temperature would have settled just as quickly had the sulphathiazole been continued. However, with no bacteriological test and no apparent lesion causing the thrombosis in the early stages, it was not justifiable to do anything but give full doses of penicillin and a sulphonamide.

I am indebted to Dr. J. C. McEntee, acting medical superintendent, for permission to publish this case; and to Drs. Bamforth and Saward, of St. Thomas's Hospital, for generously supplying the penicillin.

Reviews

ANTIMALARIAL DRUGS

Antimalarial Drugs. General Outline. By O. Temkin and Elizabeth M. Ramsey. (Pp. 110, with Bibliography. No price given.) National Research Council: Division of Medical Sciences. Issued by the Office of Medical Information (under grants of the Carnegie Corporation and the Johnson and Johnson Research Foundation). Washington. 1944.

The war in the Pacific compelled careful revision of our methods for controlling malaria, and the loss of Java and its quinine supplies necessitated the overhauling of our choice and use of antimalarial drugs. The present volume is a careful review of the information available in the published literature about such compounds, and it has been compiled as a basis for the revision which the military situation demanded. The first part of the work describes the quinine situation in wartime, the principles on which the antimalarial compounds pamaquin (plasmoquine) and mepacrine (atebrin) were discovered, and the general pre-war opinions about antimalarial drugs as set out in the Third and Fourth General Reports of the Malaria Commission of the Health Organization of the League of Nations, issued in 1933 and 1937 respectively. A list is included of the main compounds studied during the pre-war years, with indications of their action upon avian, simian, and human malaria. Detailed summaries are given of the literature concerning the pharmacology, antimalarial activity, and toxicology of quinine, mepacrine, and plasmoquine. Subsequent sections deal with other compounds, such as thio-bismol, which show minor degrees of antimalarial action. Nowadays, when new means are being sought to produce radical cure of *vivax*-malaria, the summary of information about neoarsphenamine is timely. The antimalarial action of this compound is limited to *P. vivax*, and it does not extend to *P. falciparum*; and even with *vivax* malaria, although neoarsphenamine will usually cut short the immediate attack of malaria, most reports agree that it is no more effective than quinine or mepacrine in preventing a subsequent relapse. Antimonials, mercurials, amidines, and derivatives have all been reported to show antimalarial action under certain conditions, but in no case have the facts suggested that these compounds would be valuable for general clinical use. Owing to new information which has been gained since 1942, and which is still confined to confidential reports and military instructions, the section on "Treatment Plans of Malaria under Present War Conditions" is more valuable as history than as a guide to immediate conduct.

The review should prove valuable to the investigators who are now engaged in studying the use of the compounds under war conditions, and it is mainly for them that it has been compiled; but to the general student it would prove misleading on many points, for it omits all the newly acquired information, which is now restricted to confidential American and British reports, and which considerably modifies pre-war views in many particulars.

GENERAL THERAPEUTICS

The 1944 Year Book of General Therapeutics. Edited by Oscar W. Bethea, M.D., F.A.C.P. (Pp. 447; illustrated. 18s. 6d.) Chicago: The Year Book Publishers; London: H. K. Lewis and Co.

The *Year Book of General Therapeutics for 1944* is a useful book which can be strongly recommended to all doctors. It is small, well printed, and well written; it describes recent advances in treatment during the current year. The clarity of the exposition of difficult subjects is remarkable, and new procedures are described with caution and moderation. All the articles consist of summaries of published papers. The scope of the book can be gauged by a brief mention of some of the topics. There is a description of the use of caudal analgesia in midwifery: procaine hydrochloride in 1.5% solution is given by continuous drip by way of the sacral hiatus. There has been great enthusiasm for the method in the U.S., where it has been hailed as providing "dramatic relief of all pain" in labour. The book contains very useful sections on sulphonamides and penicillin, and a good account of the use of penicillin in syphilis. The treatment of burns is included, and antimalarial drugs have a section to themselves.

Janeway's work on the use of gamma globulin in measles is well described. This has arisen out of the work of Cohn at Harvard on the fractionation of pooled human plasma, first undertaken to provide a concentrated albumin for the purpose of giving transfusions to wounded soldiers. It has also a medical use for patients suffering from oedema because of persistent albuminuria. As a by-product of the preparation of albumin, the antibodies present in the gamma globulin fraction of human plasma have been prepared. These are a substitute for convalescent serum or adult serum in measles prophylaxis. Adult serum may carry hepatitis or other diseases due to a filter-passing agent, and some doctors do not use it for that reason. The gamma globulins carry the protecting antibodies but are free from any infecting agent.

The book also includes a clear account of the Rh factor in blood transfusion. The great progress which enterprising and able American clinicians are making in therapy at this time is well illustrated throughout.

ORAL IMMUNIZATION

Oral Methods of Immunisation. By Burton Bradley, M.B., Ch.M., M.R.C.S. (Pp. 87. No price given.) Sydney: Deaton and Spencer Pty. Ltd.

The administration of bacterial vaccines by the mouth has continued for many years without gaining general recognition as an orthodox and reliable procedure, and at the same time without suffering utter condemnation as the reverse of this. It is notoriously difficult to prove the efficacy of such a proceeding statistically, in terms of expected attacks prevented, especially when the disease is a normally uncommon one, such as enteric fever. Another method of approach is barred to us by the unfortunate lack of any dependable method of estimating immunity to most bacterial infections: the presence or absence of an easily demonstrable antibody, such as agglutinin in the blood, is almost certainly not a full and true reflection of the degree of resistance of the body. In the present state of knowledge, therefore, anyone is entitled to his opinion on this subject, and Dr. Burton Bradley in a small book published in Australia and entitled *Oral Methods of Immunisation* pronounces very strongly in favour of this method. He rightly distinguishes between two different purposes for which oral vaccines may be given—the prevention or treatment of intestinal infections, on Besredka's principle of local immunization, and that of infections elsewhere, when it must be assumed that the antigen is absorbed and immunizes the body as a whole. Bradley advocates both, and claims success in treating rheumatism and infections of the air passages and of the skin. His own experiences are only briefly described, most of the book being occupied by a chronological review of the literature of this and closely related subjects. This is strongly partisan and rather uncritical, but may be found useful as a guide to some of the literature. The book contains an astonishing number of misprints, only a few of which are corrected in a list of errata: no fewer than 19 words are mis-spelt in a list of the names of 43 journals on a single page (87).

Notes on Books

Dr. D. Haler's *Aids to Clinical Pathology* (Baillière, Tindall and Cox; 6s.) combines the functions of two previous books in this series, and covers the whole field of clinical pathology, including post-mortem technique, histology, haematology, microbiology, and biochemistry. No book of such size can be a complete guide to all these subjects, even for the elementary worker, but it contains much practical information. If we conceive the purpose of the book aright, it might be improved by recognizing that efficient work demands the use of other works on special subjects, and thus omitting descriptions of such things as animal parasites, and possibly even of individual species of bacteria, devoting the space so saved to fuller descriptions of methods of examining specimens.

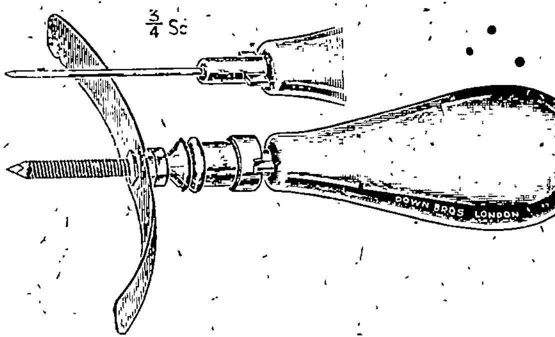
The Bacon Library of the American Hospital Association (18, East Division Street, Chicago 10, Illinois) has compiled a bibliography of the published writings of the late S. S. Goldwater, M.D. Dr. Goldwater, who died in October, 1942, was an outstanding hospital administrator. Although serving New York City as Commissioner of Health and later as Commissioner of Hospitals, the greater part of his professional life was spent as administrator of Mount Sinai Hospital in New York City. At the time of his death he was president of the Associated Hospital Service of New York City. He wrote on many subjects in the hospital and medical field. Copies of this 15-page bibliography may be had without cost from the Bacon Library.

Preparations and Appliances

A NEEDLE FOR INTRATIBIAL DRIPS

Dr. Leslie A. Gibbons writes from Redhill, Surrey:

The needle here illustrated has been made for me by Messrs. Down Bros. It consists of a hollow screw which can be screwed into the tibia (or sternum for sternal puncture) by means of the trocar-screwdriver. There are two nuts on the shaft of the needle. One nut holds a flexible metal strip and can be adjusted up and down the needle merely by twisting the nut. This is simply fixed by the other nut.



The technique is as follows. A small incision is made in the anaesthetized skin over the selected part of tibia. The metal strip is adjusted to the depth of needle required and fixed. The needle is now screwed into the tibia, fixed in position by bending the strip round the leg, and strapped by elastoplast or strapping. The trocar-screwdriver is removed and the drip connected as usual.

My thanks are due to Mr. Guy Drew, of Messrs. Down Bros., for arranging the production of the needle, and also to Mr. Norman E. Pitt, F.R.C.S.

AN OPHTHALMIC DRESSING

Dr. Allan H. Briggs, M.Sc., D.O.M.S., honorary ophthalmic surgeon, County Hospital, Lincoln, writes:

The standard form of dressing used in many hospitals for eye operation cases and injuries consists of Gamgee pads applied direct to the eye and held in position by a bandage. This has a number of disadvantages in practice. The pads tend to become soaked in serum or discharge, which adheres to any raw surface, and the soaked dressings tend to dry, forming a stiff adherent plaque, which can sometimes be detached only with difficulty. The stiffened dressings do not permit free drainage and they may become displaced, permitting the lids to be opened beneath them, sometimes with injury to the cornea of the eye beneath.

Experiments have been conducted for some time to try to devise a more satisfactory form of dressing, and it has been found that the use of a small piece of tulle gras applied direct to the injured eye beneath the Gamgee dressings is a very great advantage. The vaseline-impregnated net (in which sulphonamide or other drugs can be incorporated if desired) is easily applied and is comfortable in use. Its stickiness is sufficient to tend to keep the closed lids in position, and it permits the free escape of tears, serum, or discharge. Dressings can be easily removed and the tulle gras renewed if desirable.

No claim is made for originality in putting forward this suggestion, which must have been in use in many places already, and tulle gras is the standard dressing employed by many plastic surgeons for a number of years. The advantages and convenience of employing it as a routine dressing for ophthalmic operation cases and injuries are so marked I have felt it justifiable to give the idea some publicity in the hope that ophthalmic surgeons will find it useful.

In applying the tulle gras it is found that on cold days it is sometimes a little difficult to detach a suitable piece from the standard boxes of four-inch squares with delicate ophthalmic instruments. On the other hand, if the preparation is left to warm on a convenient sterilizer it is liable to be forgotten and too much vaseline melts out of the gauze. For convenience a special size of two-inch squares is being prepared for ophthalmic work, and they will be on the market shortly.

I have to thank the makers of several forms of tulle gras, notably Messrs. T. J. Smith and Nephew, and Messrs. Optrex, for providing material for experiment, and more particularly Messrs. Allen and Hanburys, who have been unfailingly helpful in preparing the standard two-inch-square dressings.

BRITISH MEDICAL JOURNAL

SATURDAY JUNE 23 1945

BIOSYNTHESIS OF VITAMINS IN THE HUMAN GUT

It has long been known that some animals synthesize certain vitamins either in their tissues or through the agency of their intestinal flora. Rats, cats, and dogs do not suffer from scurvy; they make their own vitamin C. Synthesis of the B vitamins has been demonstrated in the rumen of herbivora and the caecum of the rodent. This synthesis is effected by symbiotic micro-organisms, such as the cellulose-splitting bacteria. If poorly absorbed sulphonamides, such as sulphaguanidine and succinylsulphathiazole, are given to rats fed on purified diets they inhibit the growth and metabolism of the intestinal flora, which then cease their synthetic activity. By the inclusion of these sulphonamides in diets containing known members of the vitamin-B complex it has been shown that the intestinal flora in the rat can synthesize vitamin B_1, iboflavin, nicotinic acid, pyridoxine, biotin, folic acid, pantothenic acid, and inositol.[1] A fall in the level of prothrombin in the blood occurs as well, showing that these ulphonamides interfere with the production of prothrombin, probably by inhibiting the biosynthesis of vitamin K in the gut.[2] The synthesis of vitamin E by the intestinal flora has also been demonstrated.[3] This ynthetic activity of the bacteria in the gut has been confirmed by studies *in vitro*.[4]

How far do these findings apply to man? Does bioynthesis of some vitamins occur in the human intestine? The first human studies on the subject were made in 1943 by Najjar and Holt,[5] who gave nine adolescent males a ynthetic diet adequate save for vitamin B_1, which was absent from the diet. Of the nine volunteers five showed igns of vitamin-B_1 deficiency and had no vitamin B_1 in the stools. The faeces of the remaining four, who kept quite healthy, were found to contain appreciable amounts of vitamin B_1, in spite of a zero intake. Succinylsulphathiazole, which is bacteriostatic in the bowel, was given to one of them, with the result that the vitamin-B_1 content of the faeces fell to zero. This was taken to prove that vitamin B_1 was synthesized by the bacteria in the gut. Absorption of vitamin B_1 from the large intestine was assumed to occur, as a retention enema containing the itamin increased the urinary excretion of it. The validity of these studies has recently been challenged by Alexander and Landwehr,[6] who do not question the biosynthesis of itamin B_1 in the gut, but doubt whether it is absorbed from it. They have demonstrated that the vitamin B_1 in human faeces is largely within the bodies of the bacteria and not free in the lumen of the gut; so it may not be absorbed. They also state that most of the vitamin B_1 is present as cocarboxylase, which cannot be absorbed unless first dephosphorylated by enzymes which are not present in the large intestine. Alexander and Landwehr also challenge the observation of Najjar and Holt that vitamin B_1 given in a retention enema is absorbed from the large bowel. They state that the amounts used by the latter—50 mg.—were not physiological, and that physiological doses, calculated on the amount of vitamin B_1 present in the average twenty-four-hour stool, are not absorbed from an enema. Najjar and Holt's claim that the vitamin B_1 synthesized by bacteria is available to the host is supported by the observation of Gant and his colleagues[7] that some 40% of the vitamins synthesized by bacteria can be extracted from the cells by aqueous media. The subject obviously requires further investigation.

Using a technique similar to that employed in the vitamin-B_1 experiments, Najjar and his colleagues[8] have produced evidence to show that biosynthesis of riboflavin occurs in the human gut. The subjects they studied excreted more riboflavin in their faeces and urine than they took in their food. Ellinger and his co-workers[9] have also recently announced the biosynthesis of nicotinamide within the human intestine. According to them, the amount of nicotinic acid synthesized by the bacterial flora in the gut may be as much as 80% of the estimated human requirements. It has been suggested that the confusional and mental symptoms and pellagroid rashes occasionally reported after treatment with sulphonamides may be due to conditioned nicotinic acid deficiency produced by the action of these drugs on the intestinal flora. Another explanation, and a more likely one, is that the sulphonamides interfere with the respiratory enzyme systems of which nicotinic acid and other B vitamins are components. These systems are concerned with the metabolism of carbohydrate, which is used exclusively by nervous tissue as a source of energy. The mental and nervous symptoms may therefore be due to anoxia of both central and peripheral nerve tissue.

What are the clinical implications of these observations on vitamin biosynthesis? If it is true that man can utilize the vitamins synthesized in the gut, our ideas on vitamin requirements may need revision. As Najjar and Holt have shown, the degree of biosynthesis that occurs varies considerably from person to person. This might explain the divergent views held by different authorities on the human requirements of the B vitamins. Henschel and Keys,[10] for example, kept volunteers healthy on diets containing only 0.23 mg. of vitamin B_1 per 1,000 calories daily, yet others have reported deficiency symptoms on intakes greater than this. The National Research Council, U.S.A., recommend a daily intake of 0.6 mg. per 1,000 calories. There is also disagreement among nutritionists over the human requirements of riboflavin and nicotinic acid. It would seem wise to give patients receiving sulphonamide drugs supplements of the B vitamins, preferably in the form of high-potency yeast, which is rich in vitamin B₁ and riboflavin, and meat extracts, which are among the best sources of nicotinic acid. Disorders of the gut are often associated with symptoms characteristic of deficiency of the B vitamins. So-called "secondary" or conditioned pellagra has been recorded after such diseases of the alimentary tract as carcinoma, chronic diarrhoea, amoebiasis, intestinal parasitism, ulcerative colitis, and after short-circuiting operations on the intestines. Do these conditions produce deficiency symptoms by interfering with the absorption of the B vitamins, or is there some interference with their synthesis in the intestine as well? A conditioned deficiency of vitamin K, manifested by a low blood prothrombin and increased tendency to bleeding, may be produced in rats by the less soluble sulphonamides.[2] This is due to their bacteriostatic action on the intestinal bacteria that synthesize vitamin K. Haemorrhage, responding to vitamin K, has been recorded in patients given succinylsulphathiazole,[11] and it is also stated that the blood prothrombin is significantly decreased in patients taking sulphonamides.[12] Here is presumptive evidence of the biosynthesis of vitamin K in the human gut.

It was not so long ago that we all believed in the evils of intestinal stasis, with its "auto-intoxication" due to the supposed absorption of hypothetical bacterial toxins. The wheel of medical thought has turned full circle. The bacterial inhabitants of the intestine are no longer looked upon as toxin-producing parasites but as useful symbiotic organisms breaking down unwanted waste products such as cellulose and unabsorbed nitrogenous matter, and synthesizing, among other things, numerous vitamins and also protein.

LOBECTOMY AND PNEUMONECTOMY FOR TUBERCULOSIS

As long ago as 1822 Carson said of tuberculosis: "If this disease is to be cured it must be accomplished by mechanical means," and since then many mechanical measures have been employed, mostly indirect forms of attack such as compression, relaxation, and immobilization. Successful extirpation of pulmonary tuberculosis by lobectomy or pneumonectomy has, until recently, not appeared to be feasible. Since the establishment of these operations as standard treatment for bronchiectasis and carcinoma a number of cases of tuberculosis have been reported upon unwittingly, and the results were found to be so bad as to lead to condemnation of any deliberate attempts to excise a known tuberculous lesion. In 1935 Freedlander[13] reported a successful right upper lobectomy for tuberculosis, and the patient is still alive,[14] 10 years after, and "in fairly good condition." Since then a number of other reports of successful cases have appeared, notably those of Dolley,[15] and Jones,[16] and of Churchill and Klopstock[17]: these last two authors in a brilliant paper described 6 cases operated upon by lobectomy, all of which healed by primary intention.

What rapid strides have since been made is to be seen in the February number of the *Journal of Thoracic Surgery* which contains a symposium of five papers devoted to this subject and a lengthy and most interesting discussion. The problem is clearly one of great complexity, and it is as yet not possible to make any final pronouncement on the success or even desirability of the new method of treatment. The work done so far is still necessarily of a pioneer experimental nature, but it has already been shown that the initial high mortality and morbidity in the sporadic cases operated on mostly in error need not occur. Churchill and Klopstock have, indeed, emphasized the fallacy of attempting to draw conclusions from this heterogeneous group of cases Where the selection has been carefully made and a proper modern operation has been performed the results have improved so much as to place it within the realms of feasibility. In the early days of lobectomy and pneumonectomy when the tourniquet technique was being used it was inevitable that diseased tissue was left in the stump; this broke down, fistulae formed, and as a result severe empyemata and fatal contralateral spread of disease followed. With careful dissection technique so that the whole lobe or lung is removed and the bronchus accurately sutured this risk i not so much to be feared. Technically the operation in tuberculosis is said not to be so difficult as in many case of bronchiectasis and malignant disease. In the above symposium Janes, of Toronto, mentions 32 operations with 6 deaths; Maier and Klopstock, 16 cases with only 1 death and Bailey, 21 cases with 6 deaths. The largest series i reported by Overholt and Wilson, who have performed 6 resections on 61 patients between 1934 and 1943; thei operative mortality was 15.8% (10 deaths) and their case mortality up to date 24.6% (15 deaths). These authors stat that since January, 1942, when they began to use a mor modern technique, they have performed 45 resections on 44 patients with only 5 deaths (11.1%); the case mortalit to date for this series is only 13.6%. Moreover, they sa that if this new series is divided into reasonable risks and desperate risks the operative mortality was 6.3% and 43.7% respectively. Chamberlain contributes a valuabl paper on a comparison between the functional results of upper thoracoplasty and upper lobectomy. In the discussion of the papers there was some reluctance to accep resection as an alternative to thoracoplasty, seeing that th results of thoracoplasty are relatively better and the mortality lower. Most speakers felt that much was still to be learnt about dangers and indications, but, in the words o Alexander, "resection . . . has a definite place in the treatment of tuberculosis but that this place should be limite to relatively few patients for whom less risky operations which produce better results, are definitely not suitable. The indications for lung resection would at present seem to be: (1) If the disease is largely bronchiectatic and the tuberculosis not particularly active. (2) If there are cavities at the mediastinum, hilum, or lower lobe, where the prognosis for closure by other means is far from good. (3) If there are tension cavities that fail to collapse with artificial pneumothorax. (4) In some cases of persistent cavity afte thoracoplasty. (5) In stenosis of the main or of a lobar bronchus.

Pulmonary tuberculosis is such a terrible disease if uncontrolled that this new attempt to add extirpation to our methods of attacking it must arouse great interest and not a little hope of providing a good result in some of those cases which in the past have failed to respond to the orthodox methods of treatment by rest, relaxation, or compression therapy. It is clearly a method that must be used only by the very experienced, and then guardedly, and after all alternative simpler methods have been considered and rejected. At first thought it may appear to be so dangerous as to be generally unacceptable, but the results quoted above are good enough to demand serious consideration, especially as they are results obtained in the pioneer stages of the treatment.

RITUAL DEHYDRATION

> "A Wine Cooper fell into a Dropsy which resisted all the usual Methods. This Man was prodigiously swell'd, Belly, Back, Sides, Thighs, and Legs. Being past all Hopes and having on him an inextinguishable Thirst, he was permitted to drink 14 Quarts of Water in about 10 hours and in al that Time made not one drop of Urine. Soon after he began to piss; and he drank on, 4 or 5 Quarts daily, and so recovered. . . . That Water should expell Water is a Miracle beyond any of St. Winifred's. Now no man in his Senses would have prescribed such a Water course to cure a Dropsy, which shows how little we know of Nature and the great Uncertainty of our Art."*

The orthodox treatment of oedema is by restriction of the intake of water and salt. The thirsty patient usually gets used to it and is supported and sustained by his physician's belief that a waterlogged patient can hardly need still more water. This ritual practice gains further support when it is seen that oedema sometimes increases when more water is drunk. Usually salt is restricted, because if salt is absorbed more water can be retained in the body. The logical conclusion of this practice seems to be that the waterlogged patient should be given no water at all. A kindly compromise is usual, however, and the patient is allowed one or two pints daily or else enough to minimize suffering from thirst. Oedema fluid, like normal interstitial fluid, may tend to become concentrated by evaporation of water from the body surfaces when intake is restricted. Normally, the changes being reflected in the blood stream, the kidneys work powerfully to preserve the electrolyte pattern, so that if water evaporates they excrete a stronger salt solution and the internal environment is repaired. The kidneys can perform this work only if they obtain an adequate supply of water. When oedema fluid contains too much sodium salts the tissue cells become dehydrated and "thirsty" and the patient wants water. If he gets it the water naturally goes to make the cell environment again isotonic and to rehydrate the tissue cells which were "brine-logged." This beneficial rehydration may thus be attended by an increase of the oedema, enough to make the faint-hearted falter. When the "thirsty" cells and oedema fluid are satisfied the kidneys can then proceed to the repair of the electrolyte pattern and the excretion of oedema fluid.

F. R. Schemm,[1, 2] reasoning on these grounds, has treated a large number of oedematous patients by giving them enough fluid to supply the necessary surplus for adequate renal function. To promote further the elimination of surplus sodium he restricted sodium intake and gave a diet designed to produce neutral or acid end-products. It was common, in his regime, to give several litres daily to patients with oedema associated with cardiac failure or in nephrotic syndrome supposedly due to lowering of plasma proteins. Cases of oedema with congestive cardiac failure seemed to tolerate five or six litres of fluid daily by mouth or supplemented by intravenous 5% dextrose; the oedema sometimes disappeared and the patient improved on the regime after rest, digitalis, mercurial diuretics, and water restriction had proved ineffective. Benefit has been claimed in nephrotic syndrome, in pulmonary oedema with left ventricular failure, and in stubborn anasarca with chronic rheumatic carditis. Even with these large fluid exchanges it was found that needed sodium chloride was conserved by the kidneys, and only the surplus was excreted.

Schemm's results are impressive and demand critical consideration. He recommends a modest and careful trial for the timid, and persuades the conservative with apt quotations to show that tradition favours the quenching of thirst, even in dropsy. "That Water should expell Water is a Miracle beyond any of St. Winifred's . . . which shows how little we know of Nature and the great Uncertainty of our Art."

HYPOGLYCAEMIC FATIGUE

Recent developments in the study of the neuroses, which have been greatly stimulated by the war, have drawn attention to the physiological basis of many neurotic symptoms. Such conditions as vitamin-B deprivation have been found to cause symptoms ranging from minor difficulties in concentration, neurasthenic and anxiety disorders, to severe psychotic states. On the other side organic lesions, such as gastric and duodenal ulcer, previously attributed solely to physical states, have been found to be influenced by such psychological factors as worry and strain. The growing belief in the interaction of mind and body, which by some still tend to be regarded as separate entities, has led our American colleagues to elevate "psychosomatic medicine" into a new specialty, in which medical and psychiatric factors are studied simultaneously in the same patient. Of some interest in this field is a recent study by Alexander and Portis[3] of hypoglycaemia as the basis of the neurotic symptom of fatigue. They investigated a group of patients who showed a fairly consistent syndrome. Normally active and energetic, they became ill after a change in their lives which involved application to work of a new and distasteful kind. Thereafter they developed attacks of fatigue which made them almost physically incapable of carrying on with the uninteresting occupation. The feeling of fatigue would be at its worst first thing in the morning, would be somewhat relieved by meals, and would pass off almost completely after the largest meal of the day in the evening. Glucose-tolerance tests showed in all patients a distinct flattening of the curve. Though the basal blood sugar was not below normal limits, the usual elevation after administration of glucose was not found. The curve would be restored to normal after a hypodermic injection of 1/75 gr. atropine. Good therapeutic results were obtained by psychotherapy, giving a diet containing no free sugar but complex carbohydrates, and an injection of atropine thrice daily.

---

* This quotation is from Sir Thomas Witherley, President of the Royal College of Physicians, 1684-7. The "usual methods," besides purges and vomits, included the use of calomel, mineral acids, and the muriate of ammonia, but not a free use of water, even from St. Winifred's Well.

[1] *Ann. intern. Med.*, 1942, **17**, 952.

[2] Ibid., 1944, **21**, 937.

[3] *Psychosomatic Med.*, 1944, **6**, 191.

The authors believe that the syndrome consists essentially in a disturbance of the homoeostatic regulation of the blood sugar. The feeling of zest with which the healthy man faces his daily activities represents a certain tonus in the vegetative system. A more enhanced tonus of the same kind is produced by feelings of fear and rage. If zest fails, the tonus drops and any sustained activity cannot be so well maintained. The patient tries to drive himself on to activities which cause a paralysing vegetative relaxation. Vagal preponderance results in a state of hyperinsulinism, demonstrated by the glucose-tolerance test. Administration of atropine diminishes the vagal tone and shifts the balance in favour of sympathetic tonus, and so helps to break the vicious circle.

METHYL BROMIDE POISONING

Methyl bromide (CH_3Br) has a molecular weight of 94; it is a colourless mobile liquid with a specific gravity of 1.732 at 4° C. and boils at 4.5° C. The specific gravity of the gas at normal temperature and pressure is 3.27. It has a faint but agreeable odour and is colourless. It is manufactured by heating methyl alcohol with sodium bromide at 130° C. in excess of sulphuric acid, and is then washed and condensed in refrigerator coils surrounded by brine. In the chemical industry it is used in the preparation of methylic compounds and for making colours from methylated tar. It has been extensively used in recent years as a fire extinguisher, a fumigant, a refrigerant, and a delousing agent. As an insecticide of great effectiveness it can protect a wide variety of foods, grain, plants, and textiles. Entomologists favour it for the control of pests because it leaves no smell or taste behind, it is not explosive on mixture with air, it is highly toxic to insects in all stages of their development, it has a low absorption and high penetrating power, and is inexpensive. It is particularly effective in the extermination of lice, bed-bugs, and weevils.

As so often happens, however, with substances which are really effective against insects it is also toxic to man, and in the last two years many cases of poisoning have been recorded both in this country and in the United States.[1-10] The toxic effects fall into three distinct groups: those brought about by pure gassing, the systemic effects of the vapour, and the effects on skin and mucous membranes. In the first instance death may occur from anoxaemia or toxic paralysis of the respiratory centre. Mild systemic effects include headache, giddiness, numbness, fits, diplopia, inability to accommodate, and vomiting; severe effects include signs similar to alcoholic intoxication with disorders of gait and co-ordination. Methyl bromide rapidly penetrates clothing, including leather and rubber, and irritates the skin and mucous membranes, producing burns characterized by enormous blisters full of sterile fluid. Depression and sleeplessness are frequent features of the convalescent period. Usually, symptoms run parallel to the non-volatile bromine level in the blood, which may be raised from a normal not exceeding 1.5 mg. to 10 mg. per 100 c.cm.; the bromine content in the cerebrospinal fluid may also be raised from a normal of 1 mg./100 c.cm. to 15 or more mg./100 c.cm. Death, when it occurs, usually results from pulmonary oedema; and post-mortem findings include acute purulent bronchitis, inflammation and oedema of the lungs, fatty degeneration of the ganglion cells of the brain, and degenerative changes in the kidneys.

Sayers, Yant, Thomas, and Berger[11] have investigated the toxicity of the substance in animals, and Irish, Adams, Spencer, and Row[12] have shown that methyl bromide is by far the most poisonous of the four organic halides—methyl bromide, methyl chloride, ethyl bromide, and ethyl chloride. Animals exposed to lethal doses die with pulmonary oedema or, if they survive long enough, with confluent bronchopneumonia; lower concentrations produce symptoms and changes like those already described for man. While a safe concentration for methyl bromide has not so far been established, it might be assumed that 70 parts per million would be the upper safety limit for short exposures and 50 parts per million for exposures of eight hours.

Once symptoms are established treatment is of little avail, and attention must therefore be directed to preventive measures. Here difficulties arise because the gas is odourless and can pass through the ordinary Service respirator in a quarter of an hour. Clarke, Roworth, and Holling[7] suggest that some substance with a smell be added to methyl bromide in fire extinguishers to draw attention to any leak. Certainly fire fighters who use these extinguishers should be warned against spilling the liquid and instructed that any clothing wetted by it must be removed immediately. When it is used as a fumigant the trucks, ships, store-houses, barns, or other buildings must be thoroughly ventilated on completion of the process. In industry the prevention of leaks, adequate dilution of escaping gas, and exhaust ventilation through the floor of the workshop are the most important preventive measures, but periodic medical examination will not only help in the detection of early symptoms but may draw attention to dangerous mechanical parts and lead to their repair. Bathing the hands in a weak solution of sodium carbonate may help to prevent skin lesions by decomposing the methyl bromide.

As has already been announced in the *Journal*, Dr. Charles Hill, Secretary of the B.M.A., is standing as an Independent candidate for Cambridge University in the coming General Election. Cambridge graduates will be receiving Dr. Hill's statement of policy in the election address he has written. When the new Parliament meets one of the early matters for debate will be a Bill for a comprehensive National Health Service. This Bill and the Act which will follow will be of the profoundest significance to all medical men and will shape the course of medical organization for many years to come. It would be a great advantage if there were on the floor of the House of Commons a medical spokesman who has at his finger-tips all the intricate details of the organization and administration of medical services. It is also much to be wished that there should be medical M.P.s who can represent—and not misrepresent—the wishes and aspirations of the majority of practising doctors in this country. For these reasons Cambridge medical men will do well to reflect upon the present phase in the history of medicine when they come to cast their votes.

The Mitchell Lecture before the Royal College of Physicians which was arranged for July of this year, has been postponed until 1946. The Croonian Lectures will be delivered by Dr. Macdonald Critchley on Tuesday, July 10, and Thursday July 12, 1945, at 4.30 p.m.

BIRTHDAY HONOURS

The names of the following members of the medical profession were included in a Birthday Honours List published in *Supplements* to the *London Gazette.*

Knighthood

James Douglas Cooke, F.R.C.S., M.P. for South Hammersmith since 1931. For political and public services.

Sidney Valentine Sewell, M.D., F.R.C.P. Consulting Physician in the State of Victoria.

Reginald Watson Watson-Jones, M.Ch., F.R.C.S. Civilian Consultant to the Royal Air Force.

C.B. (Military Division)

Leopold Thomas Poole, D.S.O., *M.C.*, M.B., Ch.B. Major-Gen., late R.A.M.C.; Honorary Physician to the King. Director and Professor of Pathology, Royal Army Medical College.

C.M.G.

Albert Victor Bernard, C.B.E., M.D., D.P.H. Late Chief Government Medical Officer, Malta.

George Ernest Hugh Le Fanu, M.D., Ch.M. Late Consulting Physician at Liverpool to the Colonial Office.

Lucius Nicholls, M.D. Director, Bacteriological Institute, Ceylon.

Benjamin Stanley Platt, M.Sc., Ph.D., M.B., Ch.B. Director, Human Nutrition Research Unit, Medical Research Council.

Alexander Montgomery Wilson-Rae, M.D. Assistant Medical Adviser to the Secretary of State for the Colonies. Lately Deputy Director of Medical Service, Nigeria.

C.I.E.

Kombar Ramaswami Krishnaswami Iyengar, O.B.E., M.D., D.P.H. Lieut.-Col., I.M.S.(ret.). Late Director, Pasteur Institute of Southern India, Coonoor.

C.B.E. (Military Division)

William Innes Gerrard, O.B.E., M.D., F.R.C.P. Acting Surg. Capt., R.N.(ret.).

Thomas James Kelly, *M.C.*, M.D. Acting Air Vice-Marshal, R.A.F.

D'Arcy Power, *M.C.*, M.R.C.S., L.R.C.P. Acting Air Vice-Marshal, R.A.F.

Arthur Eaton Richmond, O.B.E., M.R.C.S., L.R.C.P., D.T.M. Col. (Temp.), R.A.M.C.

C.B.E. (Civil Division)

Miss **Kate Fraser**, M.D., D.P.H. Commissioner, General Board of Control, Scotland.

Bernard Hart, M.D., F.R.C.P. Consultant Adviser in Psychiatry to the Ministry of Health.

James Russell, M.B., F.R.C.S.Ed., F.R.F.P.S. Surgical Director, Emergency Medical Service, Scotland.

Robert Standish-White, O.B.E., F.R.C.S.I. For valuable services as honorary consulting surgeon, Rhodesian Air Training Group.

O.B.E. (Military Division)

Algeo Lloyd Anderson, M.B. Surg. Capt., R.C.N.V.R.

James Martin Flattery, M.B., Ch.M. Surg. Cmdr., R.A.N.

David Walker Johnstone. Surg. Capt., R.C.N.V.R.

Frederic William Kemp, *M.C.*, E.D., M.D. Lieut.-Col., N.Z.M.C.

William Parsons Lappin, M.B., Ch.B. Lieut.-Col. (Temp.), R.A.M.C.

Clarence Lucan Gray Pratt, M.D., M.Sc. Acting Temp. Surg. Cmdr., R.N.V.R.

John Rowe, *M.C.*, M.B., B.Ch. Col., late R.A.M.C.

Norman Lyon Shepperd, M.B., F.R.C.S. Lieut.-Col. (Temp.), R.A.M.C.

Malcolm Stoddart-Scott, *M.C.*, T.D., M.D. Lieut.-Col., R.A.M.C., T.A.

Frederick Harold Van Nostrand, E.D., M.B. Col., R.C.A.M.C.

Gordon Abbott Winfield, M.D., C.M. Col., R.C.A.M.C.

O.B.E. (Civil Division)

Amar Nath Chopra, M.B., B.S., D.P.H. Lieut.-Col., I.M.S. nspector-General of Prisons and Director of Health, Orissa.

Lawrence Wylie Fitzmaurice, M.D., C.M., F.A.C.S., Colonial Medical Service. Medical Officer and Bacteriologist, Bahamas.

Nutting Stuart Fraser, M.D., C.M. Consultant, St. John's General Hospital, Newfoundland. For public services.

Alistair Robertson Grant, M.D. Medical Superintendent, Emergency Hospital, Whittingham, Preston.

Harry Hastings, M.B., Ch.B. For medical and missionary services in Nigeria.

William Malcolm McAlister, M.B., Ch.B., F.R.C.P.Ed. Medical Superintendent, Bangour Emergency Hospital, West Lothian.

Peter John Macleod, M.B., J.P. Medical Superintendent, Gleneagles Hospital and Fitness Centre. For services to civil defence. Capt., R.A.M.C.

Miss **Alice Deirdre Kingsnorth Peters**, B.M., B.Ch. Senior Medical Officer, Royal Ordnance Factory, Chorley.

Moses Sendak, M.D., D.P.H. Lieut.-Col., I.M.S. Superintendent, Special Prison, Ahmednagar Fort, Bombay.

Charles Milliken Smith, M.D., D.P.H. Medical Officer of Health, Northamptonshire County Council. For services to civil defence.

Mrs. **Clara Stewart**, M.B., B.S. Honorary Secretary and Organizer, Emergency Committee for Nurses, Leeds.

Herbert Watt Torrance, *M.C.*, M.D. For medical services in Palestine.

M.B.E. (Military Division)

Charles Bernard Ball, L.M.S.S.A. Major (Temp.), R.A.M.C.

James Menzies Clow, A.M. (Gold), F.R.C.S.Ed. Major (Temp.), R.A.M.C.

William Robert Dunlop. Major, R.C.A.M.C.

Charles Vincent Scott, M.B. Major, R.C.A.M.C.

M.B.E. (Civil Division)

Miss **Dev Priya Bali**, M.R.C.S., L.R.C.P., Women's Medical Service. Deputy Inspector-General of Civil Hospitals (Women), United Provinces.

Probhat Kumar Biswas. Civil Assistant Surgeon, Bengal.

Miss **Alva Adeline Daniell**, M.B., B.S. Civil Assistant Surgeon, Civil Medical Department, Government of Burma.

Daniel George Shields, M.B., B.Ch. Area Air-raid Precautions Medical Officer, Norfolk.

John Edward Wright, F.R.C.S.Ed., F.A.C.S. Colonial Medical Service. Surgeon-Specialist, Holbarton Hospital, Antigua, Leeward Islands.

Kaisar-i-Hind Gold Medal

Bruce Lyman Carruthers, M.D., C.M., F.A.C.P. Director, Medical Centre, Miraj.

Miss **Jessie Findlay**, M.D. Principal and Professor of Surgery, Women's Medical College, Vellore, North Arcot District, Madras.

THE MEDICAL STUDENTS AT BELSEN

At a Press conference in London Dr. A. P. Meiklejohn, member of the Rockefeller Foundation Health Commission, who has been seconded to the Nutrition Section of the European Regional Office of U.N.R.R.A., described the work of the ninety-six London medical students whom he had the privilege of supervising at the horror camp at Belsen. He said that the first batch of students arrived on the last day of April, and the primary task allotted to them was the distribution of food for the starving. Until then the small number of British troops garrisoning the camp, which had been liberated on April 16, could do no more than deliver food from the cookhouses to the doors of the huts, where it was taken over by internees. The result of such a method was that, in the moral collapse which prevailed in the camp, those who were able to walk took all the food they could get and became desperately ill from overfeeding, while those who were too weak to leave their huts died because there was nobody to feed them.

How they tackled the Job

Each student took responsibility for one or more huts, comprising from 100 to 150 patients, together with about twice that number of internees at least well enough to feed themselves. The students saw to it that the food was fairly distributed. The students also set up a dispensary and started medical treatment. The daily death rate among the sick, which had remained at about 4% until May 1, fell in one week to half that figure, and in the second week to half again, and at the same time a new spirit was plainly discernible among the internees. One special body of 25 students created within the camp a hospital area in which the most seriously sick could be cared for under hospital conditions, pending removal. They showed the same vigour in the business of cleaning out filthy, verminous huts, "creosoting" the floors, and dusting it with anti-louse powder, as others showed in their more strictly medical occupations. So excellent was their initiative that within two weeks 1,200 patients had been washed, disinfected, reclothed, and returned to the renovated huts, where they were cared for entirely by the students and by volunteer nurses from among the more active internees. "It was a joy to see the change which took place in the patients," said Dr. Meiklejohn, "when they found themselves under proper ward conditions with adequate medical attention. There can be no doubt that the large majority of the patients in this students' hospital owed their lives to this achievement."

The last of the infamous huts was burned five weeks after the arrival of the first British troops in the area. For the remainder of the month the students were employed in medical work in hospital areas which now held the 12,000 surviving sick. "It is my personal belief that no other body of men could have successfully accomplished the job which the students carried out." He spoke in appreciation of the help which the students received throughout their stay from the R.A.M.C. and the camp garrison, particularly from Lieut.-Col. J. A. D. Johnston, the senior medical officer, and Brig. Glyn Hughes, D.D.M.S., Second Army.

[Dr. W. F. Collis's preliminary report on conditions at Belsen Camp and the medical problems that arose was published in the *Journal* of June 9, page 814, and a letter by Brigadier Hughes, paying tribute to the medical students, on June 16, page 857.]

Correspondence

Determination of Age Incidence of Disease

Sir,—The *Journal* of June 9 (p. 797) contains an article on civilian dyspepsia by Drs. F. Avery Jones and H. Pollak recording *inter alia* what they refer to as " age and sex incidence " of peptic ulcers, accompanied by a chart. This, they say, " shows the maximum incidence for gastric ulcer between 40 and 60, but duodenal ulcer has an earlier peak at 35 to 39."

Surely it is time to insist that clinicians should use the term " incidence " as used in vital statistics to signify the ratio of observed cases to the appropriate population at risk. So defined, the age incidence of a disease is a true measure of liability to contract it at a given age. The figures cited by the authors of this article, like those cited in so many articles still published in medical journals, show nothing of the sort. The chart referred to simply exhibits the numbers of cases observed in each age group unrelated to the age composition of the population from which they were drawn. As such they merely indicate the risk that a patient will come under the observation of the observers at a given age if (*a*) the observers remain at the same hospital; (*b*) the population from which the hospital draws its patients maintains the same age composition.

The assessment of the age–strength distribution of the effective population of a hospital might be undertaken if a hospital had at its disposal an expert demographer with a thorough grasp of the social differentials involved in population structure. To the best of my knowledge no British hospital employs one. Within the framework of private practice any valid information about liability to disease in the civilian population at a given age is therefore confined to a handful of conditions which are either notifiable or quickly fatal.

On the other hand we have the necessary data for the Army population, because the Army population has an all-in system of social medicine. With the assistance of my colleague, Jun. Cmdr. M. M. Johnstone, M.A., I have recently made an exhaustive analysis of the true age incidence of some fifty major diseases, including peptic ulcers. The results would have been available for publication if the disclosure of basic data were not, for the present, subject to security regulations. The conclusion that the age distributions of gastric and duodenal ulcer are different, and that the latter has its peak at an earlier age, is correct; and this is not surprising since the effective population reservoir was presumably the same for both sets of cases. The peak ages of risk cited by the authors are not in agreement with the results of our analysis and can carry no weight as such for the reasons given above.—I am, etc.,

Lancelot Hogben,
Deputy Director,
Medical (Statistical) Research, War Office.

Primary Atypical Pneumonia

Sir,—I feel some comment is necessary on the leading article on primary atypical pneumonia (April 7, p. 487), for such an article has wide publicity and influence, and it appears to me to leave a false impression of the disease. I would like to make the following observations based on a series of about 300 cases which have passed through my Division, situated in Italy during the past 18 months—cases which have been analysed with considerable precision.

1. Primary atypical pneumonia is not characterized by an influenzal onset; on the contrary, upper respiratory tract symptoms are absent. Cases giving a history of a cold followed by much coughing, expectoration, and central tracheal pain are descending infections of pyogenic or virus aetiology, and may cause bronchopneumonia or patchy collapse which is usually basal in situation, or influenzal pneumonia may so develop. Such cases are immediately distinguishable from atypical pneumonia by this very history.

2. To say that the disease may last from 3 to 5 weeks and that recovery is the rule is very misleading. The average duration of fever is 8.8 days, the mean range 7 to 10 days, with extremes between 5 and 15 days. Following subsidence of the fever convalescence is rapid and patients feel fit within a week thereof. Recovery is much more than the rule: there have been no deaths in this series, and such an outcome is extremely rare. Complications are equally unusual.

3. Cough is not invariable, but is entirely absent throughout the whole course of the disease in 12 to 15%. It is often mild, dry, and disturbs the patient but little, being quite different from the hacking distressing paroxysms of pyogenic bronchopneumonia. The sputum is not mucopurulent but characteristically mucoid. Purulence develops late in a minority which becomes secondarily infected, or it may appear early in patients who are already the subjects of chronic bronchitis. Conspicuous staining with blood occurs in 30 to 35%; it commonly appears between the 5th and the 7th days and may last from a few days to a week or so.

4. Symptoms referable to the chest are often absent apart from the cough mentioned: pleural pain occurs in about 20%; dyspnoea and cyanosis are rare; the respiratory rate is commonly within normal limits. These points are in contrast to the respiratory features of pyogenic pneumonias.

5. While it is true that there may be no physical signs in the chest, a careful physician will detect the tell-tale patch of crepitations in 80% of cases. These crepitations commonly appear first on about the 4th day and become obvious on the 5th day; they usually last a week or so. Dullness to percussion and bronchial breathing are rare, the former being noted in 10% of cases and the latter in but 6%. While it is true that the *x*-ray appearances are not diagnostic, they are nevertheless highly suspicious. As stated in the article under criticism, they are either diffuse homogeneous shadows o localized flocculent opacities, the two types being sometimes mixed The situation of the lesion, however, is suggestive; it is segmental occurs as often in the upper as in the lower lobes, and is not infrequent in the middle lobe or in its counterpart on the left side Multiple lesions occurred in 12%; clinical lesions with negative skiagrams in 7%. The exact figures for distribution in my serie were as follows:

Upper lobe:	%	%
Apical segment	2	42
Pectoral „	20	
Axillary „	20

6. General symptoms are like those of any other high fever, with the emphasis mostly on headache and least on limb and back pains Unlike the febrile stage of jaundice, abdominal pain is absent, but anorexia is not uncommon, and there is sometimes nausea or vomiting. Meningismus is very rare even in cases with gross headache and the cerebrospinal fluid is normal. The spleen is sometime enlarged, but this is of doubtful significance in a malarial country The actual figure in this series was 15%.

7. The temperature chart was characteristic in 63% of the cases showing a high irregular fever to about 104° F., with odd sharp swings of several degrees, sometimes occurring twice within 24 hours The temperature had a tendency to keep returning to the sam maximum figure. The end was rather sudden in 39% or it was by lysis. The fever was sustained in 13% and quotidian in anothe 13%. It was short-term in 7%, low-grade in 3.5%. Relapses usually very short, occurred in 2%.

8. The white count is of course normal. The highest total in my series was 13,500, and only 7% were above 10,000; the maximum differential polymorph count was 80%, but the great majority lay between 50 and 75, only 8% being between 75 and 80. Th erythrocyte sedimentation rate rises early and may measure 25 t 50 millimetres in one hour by the 3rd or 4th day. It may reac a maximum level of 40 to 70 during the second week, and then falls away to reach normality in about the 4th week. Cold agglutinatio tests were done on about 20 cases with entirely negative results Both penicillin and sulphonamides have no influence on the cours of the disease.

While it is agreed that atypical pneumonia may differ in its characteristics in various parts of the world in differen epidemics, I doubt very much if the type seen in Italy, whic has been so widespread among British troops and so uniform in its manifestations, is materially different from that seen a home in the last two years.—I am, etc.,

Paul Wood,
Lieut.-Col., R.A.M.C.

C.M.F.

Civilian Mass Radiography

SIR,—While welcoming discussion on the administrative aspects of mass radiography, we regret that current correspondence in the *Journal* should have been largely actuated by a misrepresentation in your leading article of April 14, which reviewed the recent M.R.C. report on civilian mass radiography, of which we are medical authors.[1] Taking some matter from its context, you accuse us of advising that "in doubtful cases medical directors of the unit must often decide from one interview and radiograph not only whether the subject has pulmonary tuberculosis but also whether the disease is active," and you comment that "anyone who has had experience in a chest clinic will realize the absurdity of this suggestion." Had you read the report with a little more care you would have observed incidentally that one of us does, in fact, administer a large chest clinic. On the particular point in question we suggested that in the initial medical interview (which, of course, includes a history and clinical examination, accompanied by a full-size radiograph) the medical director should take the responsibility of a decision only in cases where he is in no doubt, such as calcified primary or obviously healed apical tuberculous infection. After all, this is only what is done every day in ordinary chest clinic and out-patient practice. All cases where, however, there *is* a doubt should be referred for the fullest investigation, and, if indicated, prolonged observation, either at their local chest clinic or in the unit itself, according to local arrangements. Similarly, the classification of the cases recommended in the report takes cognizance of the results of this fuller investigation.

You also take us to task for failing to throw more light on the fate of the symptomless lesion. To provide such information would have necessitated a delay of publication for a year or more, whereas, as stated in the M.R.C.'s preface to the report, the first object was to discover the technical, administrative, and social problems arising from civilian mass radiography, and to establish provisional methods and procedures, in order to assist those responsible for the routine of the national scheme. This material had to be collected quickly, and it has formed the basis for the Ministry of Health organization which has trained the various local authority teams.

In your final paragraph you pose the question whether this new method is merely to be regarded as "an interesting toy, with a useful propaganda value, or is to be used as an instrument of scientific research." We submit that scientific research is incidental to mass radiography, but that enough is known already to establish it as a practical technique for detecting hitherto unsuspected sources of tuberculous infection on the one hand, and cases of early and treatable disease on the other. It should therefore become an indispensable adjunct of the antituberculosis service.—We are, etc.,

P. D'ARCY HART.
PETER KERLEY.
BRIAN C. THOMPSON.

Newer Concepts of Breast-feeding

SIR,—I have read the correspondence on breast-feeding with great interest, and have been impressed by the considerable divergence of views. I feel that much can be learned about breast-feeding by observing the instinctive actions and behaviour of the child before these have been influenced by the preconceived ideas of the nurse, mother, or doctor. Moreover, these observations can be well supported by comparison with the instinctive behaviour of young suckling animals.

It is commonly observed that a lamb will butt its mother's mammae before taking the nipple; a litter of piglets will appear to fight frantically over the sow's belly for almost a minute; then suddenly all will be quiet, and each piglet will be at its appointed place, fully occupied in swallowing the milk that is so rapidly and actively secreted. We do not find these very young animals attempting to suck milk from hard, engorged mammae, on which they can find no hold, or chewing the nipple. They massage and express the mammae until the inspissated secretions are forced out and the gland is pouring forth its milk freely.

The human infant, in a great number of cases, attempts to do the same thing, but is all too often suppressed by the nurse or attendant, and the mother is instructed that the child must not be allowed to "play" with the breast. The infant, even on the first occasion it is put to the breast, makes no attempt to feed, but, instead, starts to mouth or knock the breast by shaking its head from side to side, and only after doing this or making similar gestures does it attempt to suckle a breast, now suitably stimulated and softened, with milk or colostrum making its appearance. Usually, instead of this happy scene we see a busy nurse and a worried mother attempting to force a child to suck, and a thwarted baby being made to suck for ten minutes at an almost dry breast, thus causing the nipple to be overstretched and horribly chewed, thereby starting the vicious circle of cracked painful nipples and inadequate milk.

I would recommend the following procedure for the first forty-eight hours or until secretions of milk are established. The baby should be put to the breast and allowed to "play" for as long as it cares to, only being restrained from chewing the nipple. When it does start to suck it should only be allowed to continue for one minute at each breast. This, together with the massage when "playing," is enough to give the necessary stimulation to lactation, and remove colostrum without causing damage to the nipples. When the milk begins to be secreted in quantity it will usually be found that the child's instinctive actions before suckling will be sufficient to release the tension in the breast, and start the flow of milk *before* it starts to suck. If, however, these instinctive actions are not adequate or well developed they should be supplemented by the mother herself starting the flow of milk by manual expression, thus imitating the natural behaviour of the child or young animal. The loss of milk is insignificant, but this unnatural expedient should not be allowed to replace the child's natural and instinctive stimulation of the milk flow before suckling.

Both breasts should be fed at each nursing if maximum supply of milk is wanted, and I agree that the routine suggested by Dr. Michael Pallot (May 19, p. 714) is the best one to be followed. In support of the reason he puts forward it should be furthermore noted that many women with well-established lactations will actually secrete and lose a quantity of milk from the second breast while the first is being suckled, indicating that the stimulus to lactation is bilateral.

I have limited my reasons for suggesting the above systems to a physiological basis, but I feel that an equally strong case could be adduced for its support from the psychological angle. —I am, etc.,

C. R. NAISH,
B.L.A. Flight-Lieut.

Women in Labour

SIR,—From the recent correspondence on this subject it is apparent that the general consensus is in favour of analgesics in labour. It is also agreed that, for some reason, analgesics are not being given in this country to the majority of women in labour who require alleviation.

Various aetiological factors have been cited for the present lamentable state of analgesia in labour—e.g., "Youth at the Helm," young women medical officers of health, callous midwives, lack of apparatus, etc. I agree with Dr. Galley (May 12, p. 678) that the experienced midwife and medical attendant tend to become "conditioned to . . . imperfect analgesia—or none at all—in the labour ward," and are liable to sink into a state of apathy and conservatism if not occasionally stimulated by the natural reactions of the young inexperienced pupil midwife or medical student. From my knowledge of midwives I think it is grossly unfair to label them as callous and to lay at their door the failure of the medical profession, until recently, to provide them with an effective analgesic. This, of course, is the crux of the whole matter, and the only aetiological factor of importance. Provide an effective but harmless analgesic which can be administered by midwives by means of a simple apparatus—preferably foolproof—and the bogies of apathy, prejudice, callousness, etc., will disappear.

It has been stated in Whitridge Williams that, "in spite of advances in this field, the multiplicity of drugs and methods of their administration and the lack of uniformity in therapeutic response indicate that as yet we have no ideal method which produces complete alleviation of pain and at the same time is entirely safe for both mother and child." Gas-and-air analgesia is safe in the normal case, but should not be used in cases of heart disease or toxaemia of pregnancy. But I believe that, even with care, adequate preliminary instruction, and intelligent co-operation, its analgesic properties are disappointing. In America interest in caudal analgesia has been revived—a certain indication of desperation. Anyone considering this method should first read Prof. F. J. Browne's letter (May 26, p. 746).

Dr. Galley refers to conservatism as a bar to progress. Here surely is an excellent example. Trichlorethylene has long been recognized as a potent analgesic agent. Hewer states that it exerts "the most potent and rapid analgesia of all the volatile drugs with which I am familiar, including nitrous oxide." Dr. Elam reported favourably on trilene analgesia in midwifery in the *Lancet* in 1942, and this was followed up by an excellent article in the same journal (Dec. 4, 1943) by Dr. A. Freedman describing his results in 190 cases using an inhaler of his own design. The inhaler is inexpensive, portable, foolproof, and has been proportioned to ensure that a mixture of trilene and air of only analgesic potency is inhaled. In his conclusion he states that "adequate analgesia safe for mother and infant was provided by the inhaler. There seem to be no contraindications to its use. It could be used by suitably trained midwives." He met with no complications due to this method of analgesia and suggested a wider investigation. Dr. D. C. Devitt also reports favourably on trichlorethylene in midwifery in the *Journal* of March 24 (p. 422).

On reading the replies to Dr. Elam's letter one is struck by the absence of constructive criticism and by the inference of Dr. Florence McClelland's question (April 28, p. 607), "How many of our number who undertake the care of an expectant mother have taken the trouble to make themselves thoroughly conversant with all the analgesic techniques at our command to-day?" No; trichlorethylene has only been mentioned to be condemned (Dr. W. J. Clancy, April 21, p. 565). I myself, I regret to say, have only recently started using trilene as an analgesic in labour. It has been used in my department for 80 cases. Freedman's technique has been closely followed and his inhaler has been used. In this short series of cases the findings have been as follows:

1. Satisfactory analgesia in over 90%. Quite a few patients were quite oblivious of the actual birth.
2. It can be given for long periods without ill effect—e.g., 7–8 hours.
3. No complications seen due to the analgesic and no ill effects in cases of mitral stenosis, toxaemia of pregnancy, and bronchiectasis.
4. The uterine contractions, pulse, blood pressure, and respiration rate were not affected.
5. Nervous patients relaxed well during the first stage and also during the delivery of the head.
6. Even when the analgesic effect was very marked and the patient became drowsy, very good co-operation was obtained. The patients were quiet and obeyed instructions. Occasionally during the second stage the patient used her accessory muscles of expulsion to better advantage if the inhaler was temporarily removed.
7. Very rapid recovery from analgesic; no after-effects.
8. Practically all the babies were born in good condition, and many cried lustily during or immediately after birth even in the cases of mothers who had inhaled trilene deeply and for long periods. One baby was smelling strongly of trilene but its respirations and colour were good. In any baby which was cyanosed or apnoeic there was always another explanation possible apart from the analgesic—e.g., cord tightly around the neck.

In conclusion I endorse all that Dr. Freedman has said and appeal for further trials with this excellent analgesic so that eventually it can be put into the hands of the much-maligned midwife, together with the blessing of the Central Midwives Board.—I am, etc.,

Leicester. D. R. CAIRNS, M.R.C.O.G.

Puerperal and Lactational Mastitis

SIR,—Following the article by Dr. A. A. Fulton (May 19, p. 693) it may be of interest to give similar figures for Birmingham for the past seven years. As in Dundee, the investigation has been made by means of notification by health visitors in addition to information received from midwives, hospitals, and nursing homes. Only cases showing suppuration are notified.

The incidence of mastitis appears to be very much lower in Birmingham than in Dundee. Although the percentage of cases occurring in patients delivered in hospital is greater than in patients delivered at home, it is still very small compared with the 16% found in Dundee. The incidence of mastitis for the City of Birmingham during this seven-years period (129,657 confinements) would appear to be 0.6%: that for cases delivered in hospital being 0.8% and for cases delivered at home 0.4%. The following table sets out the yearly fluctuations:

Year	Confinements at Home		Confinement in Hospital or Nursing Home	
	Confinements	Cases of Mastitis	Confinements	Cases of Mastitis
1938 ..	10,906	62	6,684	92
1939 ..	11,749	55	6,325	67
1940 ..	9,748	46	6,957	59
1941 ..	8,864	34	5,667	38
1942 ..	10,422	36	8,188	43
1943 ..	11,248	23	9,581	45
1944 ..	12,125	87	11,193	95
1938–44 ..	75,062	343	54,595	439

—I am, etc.,

City of Birmingham Public Health Department. V. MARY CROSSE, M.D.

Anaesthesia for Caesarean Section

SIR,—I have read with interest the letter by Dr. Kinkead Allen (June 2, p. 784) on the subject of anaesthesia for Caesarean section, but feel that any advantages of his technique are far outweighed by its possible complications. Even with great experience the abdominal field-block described is a time-consuming manœuvre, and during this time one would gather that "to prevent the parturient being distressed by the theatre display, needle pricks, etc. . . . she is kept from moving her limbs by the very lightest chloroform or vinesthene narcosis." Surely the dangers of light chloroform narcosis have been aired in public for many years, and a light vinesthene narcosis kept up for 20 to 30 minutes before the uterus is opened cannot fail to have some anaesthetic effect on the baby. Furthermore, Dr. Kinkead Allen gives his patients 15 mg. (1/4 grain) of omnopon or morphine before the operation, a practice which so far as I know is universally condemned in view of the very real danger of foetal apnoea.

I have yet to find a better anaesthetic for Caesarean section than nitrous oxide and oxygen, supplemented if necessary by di-ethyl ether, the only premedication being atropine 1/100 gr. True, a skilled administrator is necessary, but anyone who can give safely "the very lightest chloroform or vinesthene narcosis" should be able equally to administer gas-and-oxygen. In the classical operation I have frequently seen the baby born within 3 minutes of commencing the anaesthetic, and in the lower-segment operation there is usually only a 6–7 minute interval. The baby almost invariably cries lustily at birth, and the uterus contracts well. If it is so desired it is quite easy to have the patient conscious before she leaves the theatre.

The possible disadvantages of gas-and-oxygen are post-operative pain and restlessness and the absence of relaxation unless a dangerous degree of anoxia is permitted. The former is usually well controlled with a rectal drip containing 30 g. each of potassium bromide and aspirin; as for relaxation, the abdominal muscles have in any case been well stretched during pregnancy, and the majority of obstetricians do not consider that complete relaxation is necessary in Caesarean section.—I am, etc.,

London, E.C.1. J. KENNETH IRVING.

Atropine for Toxic Effects of Prostigmin

SIR,—The recent correspondence on carbachol and its antidote following the annotation in the *Journal* (May 5, p. 636) prompts me to send the particulars of the following case, where toxic effects of prostigmin were abolished by injections of atropine. Prostigmin differs in its action from carbachol in that it acts by antagonizing cholinesterase and thus increasing the action of acetylcholine. The toxic effects of prostigmin are similar to those of carbachol, though the action is somewhat different, the former acting by potentiating the acetylcholine already present, the latter by producing an additional acetylcholine-like stimulus. In both cases a muscarinic and nicotinic action will be obtained.

A boy aged 4½ was admitted for investigation and treatment as a case of megasigmoid, ? Hirschsprung's disease. He had previously had a colopexy done, but no improvement had ensued, so medical treatment was instituted, using the method of Klingman. Treatment with prostigmin orally was started, 5 mg. three times a day being given for two days and then 7½ mg. three times a day for two days. On the fifth day he had 10 mg. three times a day, the last dose being at 10 p.m. Until then there had been no effect. During the following night he slept well, with a normal pulse rate from 90 to 100. He was wakened at 6 a.m. and given a small soap-and-water enema. Following this he vomited four times and complained of abdominal pain. By 7 a.m. his pulse had become irregular, though remaining still at 90. He became increasingly pale and irritable and sweated considerably. The pulse decreased in volume and his face began to twitch. He seemed very shocked, and as the enema had had a moderately good result this was at first thought to be the cause, particularly as the symptoms had occurred so long after the last dose of prostigmin. He was watched until 11 a.m. His condition remained unchanged. He was then given 3 minims of adrenaline (1 in 1,000) and 1/150 gr. of atropine subcutaneously. The effect was very marked; the pulse improved and his colour returned within thirty minutes, and during the following hours he steadily improved and became more co-operative. At 2 p.m. he was given a further 3 minims of adrenaline (1 in 1,000) and 1/100 gr. atropine subcutaneously. By 5 p.m. he had fully recovered.

The toxic effects of prostigmin are discussed by Goodman and Bruckner, the latter personally having toxic effects after experimentally taking 45 mg. by mouth. Symptoms developed within two hours; slowing of the pulse was marked, dizziness, restlessness, and fear of impending death were symptoms and were associated with tremors and tonic contractions of muscles. Treatment with atropine 1/50 gr. intramuscularly restored the patient partially within 45 minutes and fully within two hours.—I am, etc.,

J. DONALD CRUIKSHANK.

Formalin Treatment of Diphtheria Carriers

SIR,—In my annual report for 1939 to my Councils, I reported, among other matters, as follows:

> I have instituted a treatment for diphtheria nose-and-throat carriers which is proving successful. The patients are given the treatment twice a day for approximately seven days, while in hospital, and are then swabbed prior to discharge—over 90% have been cured in seven days, the remainder after 14 days' treatment. The treatment is also given twice daily for approximately seven days, as below, without swabbing. My Council have agreed to pay 5s. to medical practitioners for this treatment for all *first contacts* of a diphtheria case.
>
> The treatment is given at the patients' own homes and they are allowed to carry on their own duties while receiving the treatment, except in special cases of persons working in food stores and schools, etc. In these cases swabs are taken of direct contacts, and, if positive, they are removed to hospital.
>
> Prescription for formalin special treatment as follows: Formaldehyde 11%, gelatin 2%, industrial spirit 15%, ol. menth. pip. 1%, aq. dest. ad 100%. This has been costed at the rate of 4s. per quart.
>
> Special formalin solution for the treatment of diphtheria (nasal and throat) carriers: *For Nasal Carriers*.—Dilute 1 in 20—i.e., half a tablespoonful to half a tumblerful of warm water. *For Throat Carriers* and as a general preventive gargle.—10 drops of solution to a half tumblerful of warm water.
>
> 1. The patient should blow the nose hard.
> 2. A cotton-wool compress is lightly twisted with a point about 4 cm. long, so as to remain porous.
> 3. The plug is impregnated with a solution of formalin special treatment, 1 in 20, and the plug gently inserted well into the nose. The plug should remain in position for half an hour, and care should be taken to see that the patient does not move the plug from position.
> 4. During this time the patient should gargle with a solution of formalin special treatment (10 drops to half a glass of water).
> 5. At the end of half an hour the plug is removed. To avoid re-infection the patient must be forbidden to touch the nose. With children it may be advisable to bind the fingers with sterile dressing.
> 6. The treatment is repeated twice daily until at least one negative nose-and-throat swab is obtained. (Hospital cases only.)
>
> In cases where the formalin treatment is unsuccessful:
>
> 1. A virulence test is carried out, and, if cases are non-virulent, these are discharged; if virulent, formalin treatment is continued or action taken as para. 2 below.
> 2. Certain children, having unhealthy tonsils or adenoids, are suitably operated on, resulting in negative swabs.

Since late in 1938 the above treatment has been carried out in my isolation hospital with great success; out of 39 nose and/or throat carriers treated 36 were negative (one nose-and-throat swab) after seven days' treatment; 3 were negative (one nose-and-throat swab) after fourteen days' treatment. In addition, many general practitioners in my districts have assisted me by carrying out with great success the treatment as outlined above. I have tried the "formalin treatment" in a few cases of haemolytic streptococcal carriers and meningococcal carriers with success. Perhaps others would care to try this treatment out, though I realize much research work has still to be done in the matter of "carriers" generally.

I have to thank Miss Minty, matron, Dutton Isolation Hospital, for the supervision of the treatment and the careful records kept.—I am, etc.,

E. N. HILLMAN GRAY, L.R.C.P.&S., L.M., D.P.H.
Medical Officer of Health, Runcorn Urban and Rural Districts; Medical Superintendent, Isolation Hospital, Dutton.
Runcorn.

Sexes in Dispersion of Intelligence

SIR,—I was much interested in Dr. Fraser Roberts's article on the difference between the sexes in dispersion of intelligence (May 26, p. 727). For many years the doctrine of greater male variability was regarded as a fundamental biological law and was believed to hold for all traits—physical as well as mental. Havelock Ellis wrote: "From an organic standpoint, therefore, women represent the more stable and conservative element in evolution . . . in men, as in males generally, there is an organic variational tendency to diverge from the average; in women, as in females generally, an organic tendency, notwithstanding all their facility for minor oscillations, to stability and conservatism, involving a diminished individualism and variability."

Karl Pearson was among the first to challenge the adequacy of studying sex differences in variability by a comparison of the extremes of the distribution. He called attention to the needs for direct measurement of variability around the average in large groups of unselected subjects. He and many others like Hollingworth and Montague found no clear evidence of greater male variability.

Dr. Fraser Roberts maintains that the result of the Scottish Council's survey and his own investigations put "all legitimate doubts at an end" and that "the existence of the difference is abundantly demonstrated." As selective factors are often difficult to detect and to control, I doubt whether even this careful analysis is fully convincing. For instance, can the difference in the developmental rate of boys and girls be lightly dismissed? Should not the developmental stage rather than the chronological age be the basis for comparison? In the sampling, has the difference of the social background and environmental stimulation been duly taken into account? Further, as sex differences in so-called general intelligence are probably attributable to differences in special aptitudes, could the apparent sex differences at both ends of the scale be due to the specific test material mentioned?

Group differences at high schools may be explained by the more rapid elimination of boys than girls; boys whose academic work is not satisfactory are more likely to leave school and go to work. The preponderance of males in institutions for mental defectives is probably due to the fact that house-work, prostitution, and marriage provide a means of livelihood for the feeble-minded woman, whereas boys in competitive work will much sooner reveal their mental deficiency.

Finally, as mental testing cannot provide any means of distinguishing between the effects of innate capacity and environmental influences on a person's general intelligence, it seems that much research will be necessary to ascertain the influence of different cultural *milieux* on the question of sex differences in variability of intelligence (cf. Mead, M., *Sex and Temperament in Three Primitive Societies*, 1935).—I am, etc.,

London, W.1. T. A. WERNER.

A Lesser Operative Procedure

Sir,—I was much interested in Brigadier Donald's article (June 9, p. 802) on a lesser operative procedure in the diagnosis of doubtfully penetrating abdominal wounds. It recalled an even lesser operative procedure I devised in cases of (?) ruptured malarial spleens, which were fairly common among the Asiatics in Malaya (in 1916). The method consisted of: (1) infiltration with local analgesic (subumbilical). (2) Insertion of a trocar with cannula. The withdrawal of blood was followed by immediate splenectomy.—I am, etc.,

Sarah Winstedt,
Factory Medical Officer, R.O.F.

Housing the Returned Consultant

Sir,—While sympathizing with Major H. B. Stallard (June 2, p. 787) I should like to put forward an alternative suggestion, that consultants should seek accommodation elsewhere, leaving Harley Street and the surrounding neighbourhood to the "others." Many of us before the war were paying high rents for accommodation in an area inconvenient alike to ourselves and to our patients, merely because of the "Harley Street tradition." It would be a good thing for this "tradition" to be broken, and for everybody to realize that a man (or woman) was a "specialist" on account of his (or her) professional qualifications, not on account of having a room in Harley Street.—I am, etc.,

Ferring-by-Sea.

T. W. Preston,
Lieut.-Col., R.A.M.C.

Sir,—Major Stallard's letter has excited my sympathy and understanding. The future of practice is indeed full of doubt for consultants returning from the Forces, particularly as living and consultant accommodation is almost unprocurable except perhaps at a prohibitive rent. This also applies to the Bayswater and Kensington areas as well as the area between Oxford Street and Marylebone Road, as I have discovered in many unproductive searches.

But I wish to point out that there is another service—the Emergency Medical Service—where senior full-time officers, some of them also on the honorary staff of teaching hospitals, did, on the outbreak of war, offer their services to the national call and in doing so terminated their civilian practices and left the West End, where they had lived and worked, and migrated to emergency hospitals in suburban and county areas. There they have been for nearly six years, doing what was asked of them and not permitted any contact with private work. Now they contemplate returning to their previous occupations, both hospital and private, and find it quite impossible to discover any form of living accommodation from which to restart. Speaking as one of these I hope our plight will be recognized equally with the doctors returning from the fighting Services. Most of us are in the sixth decade of life, our commitments are great, and time left to us to try and rehabilitate our fortunes is short.

I am in strong agreement with Major Stallard that some official effort should be made to requisition houses and flats quickly to make room for us who need to return in the imminent future. There is far too much accommodation occupied by offices and gentlemen of foreign extraction. It seems our claims—those of fighting Services and Emergency Medical Service alike—should come first and receive sympathetic and rapid attention.—I am, etc.,

Orpington Emergency Hospital.

Eric A. Scott.

At the annual meeting of the Yorkshire Council of the British Empire Cancer Campaign, held in the Algernon Firth Institute of Pathology at Leeds, Sir Harold Mackintosh expressed from the chair the hope that they would soon be able to step up very considerably the range of their research work. Reports on the progress of research at Leeds University by Prof. R. D. Passey and at Sheffield University by Prof. H. N. Green were received. Mr. James Phillips suggested that there should also be co-operation with the Bradford Radium Institute, and the chairman said this would be given immediate consideration.

Obituary

N. BISHOP HARMAN, LL.D., F.R.C.S.

We have to announce with deep regret that Mr. Bishop Harman died at his home near Edenbridge on June 13 after a long and trying illness. The British Medical Association has always had the good fortune to enlist for its high offices men of outstanding personality and intellect, and among such men Bishop Harman stood out as one of the most many-sided and distinguished. He was treasurer for a far longer period than any previous holder of that office—from 1924 to 1939—but he did notable work for the Association in many other capacities—for example, as chairman of the Hospitals and later of the Ophthalmic Committees. In his own field of ophthalmology he had an international reputation; his books were widely read, and his counsel constantly sought by public bodies. He was, moreover, a man of culture and of philosophic bent, and something of an authority on many matters of art.

[R. Elwin Neame

Nathaniel Bishop Harman was born in London on St. George's Day, 1869. He was educated at the City of London School and after a few years in business went up to Cambridge, where he was Hutchinson research student and foundation scholar of St. John's College, and later demonstrator in the university school of anatomy. After training at the Middlesex Hospital he qualified in medicine in 1898, and took the F.R.C.S. in the same year. He served as a civil surgeon with the Field Force in the South African War, and received a medal and five clasps. Returning to London, he soon distinguished himself in ophthalmology. His work is well summarized in the illuminated address presented to him, with the Gold Medal of the B.M.A., in 1931:

> "The list of your contributions to ophthalmological science and practice is a very long one, but your name is specially associated with the subjects of the prevention of blindness and the education of children with very defective sight. In both of these you are an acknowledged pioneer, and you have had the gratification of seeing the methods advocated by you adopted in many parts of the world. The practical results are seen not only in the compulsory notification of ophthalmia neonatorum, a measure which has led to a great reduction of blindness from this cause, and in the special classes in London for the education of children suffering from high myopia and other forms of defective sight, but in similar schools at home and abroad. This work has been recognized by many bodies interested in the prevention of blindness, both here and in other countries. The British Medical Association gladly places on record its appreciation of this good work inaugurated and carried out by you with characteristic enthusiasm. . . ."

It was his little book *Preventable Blindness* (1907), together with some Parliamentary lobbying, which was largely responsible for making ophthalmia neonatorum a notifiable disease, a measure which, owing to the care thereby made possible, did much to reduce the disease as a cause of blindness to very small proportions. In 1920–2 he served on the Departmental Committee charged with the study of the causes and prevention of blindness. The report of that committee was greatly influenced by the results of his work for the blind under the auspices of the London County Council, to whose education department he gave many years of service, latterly as ophthalmic consultant. As far back as 1908 in London he established a class for children with defective vision. Until that time children whose vision was faulty were taught in the ordinary classes, to the detriment both of their sight and of their educational progress. The "sight-saving classes" under the L.C.C. have now been copied all over the world, especially in the United States, and have been advocated in League of Nations reports. A revolution has been brought about in the methods of teaching and training short-sighted children. During the B.M.A. Meeting at Winnipeg in 1930, when he was president of the Section of Ophthalmology, Bishop Harman found himself ranked as a celebrity because of his part in the introduction of these classes.

Among the posts he had filled were those of lecturer in ophthalmology at the West London Postgraduate College (where he was at one time dean), ophthalmic surgeon for many years to the West London Hospital and to the Belgrave Hospital for Children, and consultant to the National Institute for the Blind. His *Aids to Ophthalmology*, which has been translated into other languages, reached its eighth edition in 1935. *The Conjunctiva in Health and Disease* embodied the record of some research work and was published in 1905. *The Eyes of Our Children* was one of Methuen's Health Series, published in 1915, and in addition Bishop Harman contributed many articles on ophthalmology to this *Journal* and to special periodicals. One article in his characteristic style appeared in our Educational Number for 1924 and gave advice to those intending to specialize in ophthalmology, either exclusively or in addition to general practice, which may be still referred to with profit. Mention should also be made of his ingenuity in devising new instruments for the use of ophthalmic surgeons. Several widely used constructions bear his name.

Work for the B.M.A.

Bishop Harman joined the British Medical Association immediately on qualification. His early experience of active work in its behalf was in the Marylebone Division and the Metropolitan Counties Branch, and he served both Division and Branch as honorary secretary and treasurer, becoming eventually chairman of the Division, and in 1922–3 Branch president. He was a member of the Representative Body at its first meeting in 1903, but until the National Insurance Bill of 1911 his appearances there were occasional. In 1915 he became a member of the Council, and an arduous period of service began in that year, when, with Dr. Alfred Cox, he served as joint secretary of the Central Medical War Committee. This committee, which sat until 1919, had the delicate and onerous task of organizing the medical profession so that the Government could employ every doctor able to serve his country in such a manner as to turn his qualifications to the best use. Its register took the place, so far as the medical profession was concerned, of the general scheme of attestation for male citizens. The experience thus gained was of the utmost value in organizing medical man-power before and during the present war.

His next great piece of Association service was the framing of the first Hospital Policy. As chairman of the Hospitals Committee from 1920 to 1924 it was his hand that was chiefly felt in its initiation and advocacy. He described it as a thrilling experience to pilot the hospital policy through the Annual Representative Meetings. Others who remember the wearisome debates of those years may have a different impression, and the late Dr. Henry Wallace, who was Chairman of the Representative Body at the time, publicly described them as a nightmare. The debates were detailed and lengthy, and the policy was at first received with less than enthusiasm; but it is now recognized as a statesmanlike anticipation of the inevitable results of economic changes affecting the hospitals of the country.

In 1924 Bishop Harman was elected by the Annual Representative Meeting Treasurer of the Association, a post which made a strong appeal to him, and he expressed the hope that at the end of his "first" five years of office they would not be disappointed with "the man who held the bag." The five years extended to fifteen, and there was no disappointment. He became Treasurer just before the Association entered into possession of its property in Tavistock Square, though the cheque in payment of the house was signed by his predecessor, the late Dr. G. E. Haslip.

The removal from the Strand and the successive acquisitions and enlargements in Bloomsbury were a new phase of activity for the Association, and it was an immense advantage at such a time to have in charge of the purse a man who, with many other qualities, had been trained in business and could handle real estate and the realization of investments in stocks and shares with courage and foresight. During the same period the expanding membership and prestige of the Association were reflected in a balance-sheet of multiplying figures, on the debit as well as the credit side, and it was due to his careful husbanding of resources, and the masterly—often masterful—spirit in which he guarded the funds that a difficult, even a critical, time was passed through without any impairment of the essential work of the Association. In former years the finance of the Association was a favourite target for some critics in the Representative Body, but gradually they lapsed into silence, fascinated perhaps by the engaging presentation of the figures by the Treasurer, even if not quite convinced. As Treasurer also of the National Insurance Defence Trust Bishop Harman watched the stock markets with a shrewd eye, always investing to the best advantage the accumulating income.

For many years Bishop Harman was chairman of the Ophthalmic Committee of the B.M.A., and when later a Group of Practitioners of Ophthalmology was formed he was chairman of the Group Committee which took the place of the other body. He was always a doughty opponent of sight-testing by the medically unqualified optician. It was on his proposal that, in furtherance of the policy that the practice of sight-testing by other than qualified medical practitioners is not in the best interests of the public, approval was given in 1929 to the establishment of what is now known as the National Eye Service, which provides for persons insured under the National Health Insurance Act and others of like economic status an ophthalmic medical examination and any necessary glasses at fixed inclusive charges. He persuaded the Association to make a loan to the National Ophthalmic Treatment Board for organization and propaganda, and he had the satisfaction of reporting in due course the full repayment of the loan, which had enabled an excellent piece of work to be carried through. He took great pains over the periodical investigation and analysis of cases obtained for treatment through the medium of the Board as proving what a large proportion of cases in which persons complained of eye strain were due to something more serious than errors of refraction.

Bishop Harman was the nominee of the British Medical Association for the vacancy of direct representative on the General Medical Council caused by the death of Sir Jenner Verrall in 1929, and he was elected, obtaining nearly 12,000 votes. Later he became also a member, and treasurer, of the Dental Board.

In addition to his work on the Association's behalf he was a generous donor. In 1924 he presented the Treasurer's golf cup, which is competed for at Annual Meetings. In 1929 he presented the symbolic staff for use on all ceremonial occasions. The device is a serpent of silver above a shaft of English oak, with the initials "B.M.A." To this device he gave a great deal of thought. An artist himself of no small merit with the pencil, his knowledge of architectural decoration was of wide range, and no one in the Council spoke with more decision on such matters. The memorial gates of wrought iron in the courtyard of Tavistock Square owed much to his suggestions. In his generous attitude to the Association he was warmly supported by his wife, who in 1926 endowed the Katherine Bishop Harman Prize to be awarded by the Council for the encouragement of research into the disorders incident to maternity. Mrs. Bishop Harman, herself a medical woman, is a daughter of the late Arthur Chamberlain, of Birmingham, brother of Joseph Chamberlain.

A prominent member of the Unitarian body, Bishop Harman was elected in 1937–8 President of the General Assembly of Unitarian and Free Christian Churches. He often occupied the pulpits of his Church, and his addresses and articles on religious subjects were marked by the reflective habit of his mind and his skill in the simple illustrative exposition of what he saw as the truth. Whether his views commanded assent or not, he was always original and refreshing. A ready—almost too fluent—speaker, he was never a "big gun" on the platform, but he had a happy way with him which put his opponents in good humour even when it did not persuade them, and he was skilful in the use of kindly satire at which the victim laughed as much as any. Sometimes his eagerness in debate and his enjoyment of subtle juxtapositions led him into impulsive judgments and argumentative fallacies, and every now and then he seemed to be speaking with his tongue in his cheek. Perhaps his light-heartedness prevented some from appreciating to the full the solid work which he did and the deep seriousness which lay behind that gay exterior. He will be long remembered as a public-spirited man of great versatility and charm, a cheerful philosopher, and the best of friends.

HENRY R. KENWOOD, C.M.G., M.B., D.P.H.

We regret to announce the death in retirement on June 7 of Dr. H. R. Kenwood, emeritus professor of hygiene and public health in the University of London, and honorary lieut.-colonel, R.A.M.C. He was for some time a member of the Army Hygiene Consultative Committee and civilian member of the Army Medical Advisory Board.

Henry Richard Kenwood was born at Bexhill on Dec. 22, 1862, younger son of John Kenwood, of Wadhurst, and was educated at Tunbridge Wells, in Paris, and at the University of Edinburgh, where he graduated M.B., C.M. in 1887. After taking the D.P.H. he was for ten years M.O.H. for the Finchley District, and during part of that time deputy M.O.H. for St. George's, Hanover Square. From 1894 he was also M.O.H. and public analyst for the metropolitan borough of Stoke Newington, and from 1908 M.O.H. for the County of Bedford. Apart from his administrative duties Kenwood had been demonstrator and assistant to the Professor of Hygiene at University College from 1890 to 1904, when he became Chadwick Professor of Hygiene in the University of London. He was created C.M.G. in 1918 for his services to the Army during the last war, and the Royal Society of Edinburgh elected him a Fellow. He gave the Milroy Lectures on State Medicine and Public Health before the Royal College of Physicians of London in 1918, and held office later as president of the Society of Medical Officers of Health and chairman of council of the Royal Sanitary Institute; he was also an Honorary Foreign Member of the Société Française d'Hygiène. When he retired from his post in Stoke Newington after 33 years' service he was entertained by the members and officers of the council at a complimentary dinner and received an illuminated address.

Kenwood's name is well known in the profession through the textbook *Hygiene and Public Health,* written originally by Dr. Louis C. Parkes, and through his own manual, *Public Health Laboratory Work (Chemistry),* which reached its eighth edition in 1925. "Parkes and Kenwood" appeared in an eighth edition in 1929 as "Kenwood and Kerr" to mark Prof. Harold Kerr's joint responsibility for much of the revision. Prof. Kenwood had also published papers on natural purification of sewage, sewage pollution of sea water, rural water supplies, and camp sanitation, and on tinned and potted foods. He joined the B.M.A. in 1888, was honorary secretary of the Section of Public Medicine at Portsmouth in 1899, and vice-president of the Section of State Medicine at Exeter in 1907; he had also served on one or two special committees at headquarters, and for a long period helped this *Journal* by revising the section on Public Health in the Annual Educational Number.

The Services

The Order of Polonia Restituta, Second Class, has been conferred by the President of Poland on Air Marshal Sir Harold Whittingham, K.C.B., K.B.E., K.H.P., Director-General of Medical Services, R.A.F., and that of the Third Class on Gp. Capt. Sir Louis Greig, K.B.E., C.V.O., M.B., R.A.F.; in recognition of valuable services rendered in connexion with the war.

The Efficiency Decoration has been conferred upon the following officers of the Territorial Army: Majors (Temp. Lieut.-Cols.) W. W. Crawford and A. R. C. Higham; Majors H. S. Kent and P. Weiner; Capt. (Temp. Major) P. Brookes, R.A.M.C.

Repatriated.—Capt. Samuel Lask, R.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Squad. Ldr. Harold Bernard Hunt, who died on June 10, was born on Sept. 14, 1911, and studied medicine at Birmingham University, qualifying M.B., Ch.B. in 1935. He proceeded M.D. in 1937 and M.R.C.P. in 1938. Medical posts at hospitals under various authorities, including the L.C.C., were held by him until his appointment to a commission in the Medical Branch of the R.A.F.V.R. on Feb. 27, 1940. At the time of his death he was serving at a group headquarters in South-East Asia.

Died.—Major Arthur Waymouth, R.A.M.C.

Killed.—Temp. Surg. Lieut. A. McC. Vaughan, R.C.N.V.R.

Killed in motor accident in Italy.—Major David Watson Whyte, S.A.M.C.

Medical Notes in Parliament

HEALTH NOW AND IN THE FUTURE

When presenting the survey of the health of the nation on June 12 Mr. Willink said that to discuss the proposals for a National Health Service would be out of order that day. He could, however, say that the discussions promised in the White Paper of 1944 had proceeded actively, and in so far as they related to matters requiring legislation were now largely completed. In these discussions there had been no question of any departure from the fundamental objects of the comprehensive service proposed in the White Paper, and no question of diminishing the fullness of its range or of departing from the principle of its universal availability. The discussions had been concerned with methods and with questions of the administrative structure. To describe this discussion would be out of order, but it had confirmed him in the belief that it would be possible to give effect to the scheme foreshadowed in the White Paper in a manner which would command the general agreement of those upon whose work it would depend.

Mr. Willink then gave the House a broad survey of the nation's health during the war years. It was, he said, an astonishing story when one considered how much the civil population had had to endure in the last five and a half years. The health services had had to operate under heavy handicaps. About a fifth of the medical officers of the public health services had gone into the Forces, and almost one-third of the general practitioners—the first line of defence in the health services. Public health institutions—including sanatoria, fever hospitals, and hospitals for the chronic sick—had been hard pressed, with serious shortages of nursing and domestic staff. He paid tribute to the general practitioner, who had to struggle along doing two men's work and carrying many extra burdens, such as the giving of certificates for priorities, which were inevitable under war conditions. The general practitioners had been among the most overworked men on the home front, and the country owed them a debt of gratitude.

England and Wales had had no serious epidemic. In six winters they had only one influenza outbreak, and that was shorter and less severe than the kind we had before the war. The incidence of cerebrospinal meningitis rose sharply in the early part of the war, but gradually came down again. Typhoid fever had been less prevalent than in any peacetime year, in spite of the damage by bombs to water and sewage mains, thanks to the skill of the water engineers. Generally, infectious diseases had not been so prevalent as in normal times, but there had been a marked increase in infective jaundice. The birth rate had been rising since 1941, and last year was the highest since 1925. The effective reproduction rate for 1944 was provisionally assessed at 0.990—within 1% of a full replacement standard. This was the first time such a figure had been reached since 1922. Fewer babies had died. Fewer mothers were being lost in childbirth. The chance of a baby being born dead was three-quarters of what it was six years ago. The health of the children of this country—including the school-children—had improved. The infant mortality rate last year was 46 per 1,000 births, compared with the previous peacetime low record of 50.6 in 1939.

A Less Easy Situation

For adults, the situation was less easy to assess, yet there was no evidence that they suffered to any appreciable extent. There had been an increase in tiredness and minor ill-health—the lesser ailments (from the doctor's point of view if not always the patient's). Most people were tired. They went sick more easily and recovered less quickly. Nevertheless, serious troubles had been no more prevalent and deaths from many kinds of disease declined during the war. Civilians of all ages were living as long as they did in peacetime. That calculation included deaths as a result of air raids. The Government's food policy had been one of the main factors in the maintenance of health standards. They had developed public education in matters of health, and extended the application of rehabilitation techniques in order to speed recovery and reduce disablement. They had organized a blood transfusion service which saved thousands of lives in war and could save many more every year in peace. As a result of experience with the Emergency Hospital Scheme, they knew that hospitals of all types could work together for the common good, with good will and splendid results. Mortality figures for the first quarter of this year did not maintain the improvement recorded in previous years. There was a slight setback in the infant and general mortality rates. Vigilance must be increased, and everything possible done, as quickly as resources became available, to improve the conditions which bore upon the people's health and strengthened the organization for dealing with ill-health. They could not be satisfied with favourable vital statistics. They were already trying to find out more about the extent and nature of the incidence of other forms of ill-health, particularly minor ill-health. These lesser ailments, chronic though they might be, were not shown in the records, which covered only a limited number of illnesses; and in many cases they did not come under a doctor's care. There was a slight decline in venereal diseases last year compared with the previous year, for the first time since the war. New cases were still more than double the pre-war figure. They maintained the education campaign which was started more than two years ago, and which continued to receive the approval of the majority of the public. The number of deaths from tuberculosis last year was practically the same as the pre-war low record set up in 1938. There was, however, a substantial increase in notifications of new cases compared with before the war. The problem was to provide accommodation speedily for all those who needed sanatorium treatment. They had the beds, but could not get enough nursing and domestic staff.

The Minister of Labour's problem had all along been to get nurses and domestic workers for the sanatoria at a time when other urgent needs might seem to women and girls to have stronger claims on their services. There was a shortage of nurses before the war; and during the war, in spite of the substantial addition to the total number, the demand for them had steadily increased, and it had become more difficult to maintain essential services. The end of the European war would mean the disbandment of certain services employing nurses—such as the first-aid posts—and the reduction of others. On the other hand, married nurses and others with domestic responsibilities might now be unable to continue to nurse. There was an urgent need for more nurses so that hours could be reduced. In certain services—particularly tuberculosis, mental hospitals, chronic sick hospitals, and certain emergency hospitals—the staffing position had been especially difficult. There was a shortage also of midwives. The majority of these were recruited from the ranks of the State-registered nurse, and the rising birth rate increased the demand for midwives. Every effort had been made to post nurses to services where they were most needed, including a requirement that newly qualified State-registered nurses must serve for a year in one of the fields where there was a special shortage. The need for nurses would increase.

DEATHS FROM DIPHTHERIA AND FROM BOMBS

The diphtheria immunization campaign had been most successful, though much still remained to be done. New low records of both cases and deaths had been established in each successive year since the campaign began in 1941. The number of deaths last year was less than one-third of the pre-war average, and the number of cases just over half. For every three children who died before the immunization campaign started, only one died to-day. Cases notified last year numbered 28,000 below the pre-war average and 12,000 fewer than the previous low record. This progress was more remarkable in view of the severe diphtheria epidemics throughout Europe during the war years. He had asked all local authorities to make a special effort this year to increase immunization. Local authorities, doctors, teachers, nurses, and health visitors, and the W.V.S. and Red Cross and St. John Organizations were helping in persuading parents to give their children this protection. During the war more children had been killed by diphtheria than by bombs; the figures were just under 9,000 deaths from diphtheria and about 8,000 as a result of air raids. If the majority of children under 15 years of age were immunized instead of just over half as at present, and if every baby was protected as a matter of course at 1 year old, they could get rid of diphtheria as an epidemic disease.

Doctors throughout the country had been on the look-out for possible typhus cases since 1942, when the disease began to be prevalent in various parts of the Continent and in North Africa. A special warning was then sent to medical officers of health and was recently renewed. In 1942 his Department formed a special panel of consultants with experience of typhus. The services of these consultants were available to assist in diagnosis in all parts of the country. Throughout the war medical officers at ports and air ports kept watch to prevent the entry of suspected cases. Medical officers of health maintained supervision of those newly arrived in the country who were notified to them by the port officers as possible contacts. Twenty-one cases of typhus had been diagnosed in this country: fourteen were in prisoners of war repatriated from Germany; seven in medical students who were among the 100 volunteers for special duty in the Belsen concentration camp. All these cases were promptly isolated and no secondary cases occurred. All the medical students were now out of danger. Apart from these imported cases, there had been no case of louse-borne typhus in this country.

More than 11,000 patients in E.M.S. hospitals were taking daily courses of remedial exercises. In addition, 20,000 attended hospital daily for special exercises and remedial games. Of these 31,000 receiving rehabilitation, 15,000 took part in some form of occupational therapy. Hospitals providing rehabilitation for their patients had increased to 300. The majority of Service sick and wounded received their medical rehabilitation in E.M.S. hospitals. More than 250 doctors had been specially trained. A great deal of work would have to be done by the hospitals in connexion with the rehabilitation of men and women registered under the Disabled Persons (Employment) Act. The success of rehabilitation methods was likely to lead to an increased demand which hospitals throughout the country were getting ready to meet. The Ministry of Health would retain its rehabilitation department. There had been a significant development during the war in health education. Health rather than disease was becoming news. There had been an increased demand for health educational films for showing in factory canteens and to audiences in the rural areas. They could not progress towards a healthier Britain without the backing of sound, instructed public opinion, and a wider and deeper knowledge of the proper care of personal health, and particularly the care of children.

D-DAY PLANS AND SERVICES

Speaking of the part which the Emergency Hospital Scheme took in the treatment of wounded men from North-West Europe, Mr. Willink said his Department undertook responsibility for all British Army casualties on arrival in this country. For the first time in our history provision had to be made to receive casualties in England direct from the beach and the battlefield until the Army could set up hospitals in Normandy. A few hours before the invasion nearly 1,000 doctors, nurses, and students were moved with secrecy from London to the coastal hospitals. The scheme worked smoothly. Between D-Day and VE-Day the number of casualties from North-West Europe passing through E.M.S. hospitals was 160,000. Side by side with their military responsibilities the hospitals in Greater London and the South-East treated more than 20,000 flying-bomb casualties. Many of the hospitals were damaged by bombs. Doctors, nurses, and all members of hospital and ambulance train staffs could be proud of their share in this campaign. The original arrangements included the provision of three different types of hospitals. There were, first, coastal or port hospitals at or close to the ports of disembarkation for the reception of patients unfit to travel: these contained over 1,200 beds. The second type consisted of transit hospitals, corresponding in function to casualty clearing stations, reached from the ports by road or by a short railway journey; these contained over 7,300 beds. There were, finally, home base hospitals in which patients were retained and treated to a conclusion. Home base hospitals consisted of the larger and more important hospitals in England, Wales, and Scotland, to which casualties were taken by ambulance train from the transit hospitals. A large number of beds were available in home base hospitals for the purpose, because some weeks before D-Day admission of ordinary civilian patients had been restricted to those in need of immediate treatment. Provision was also made from the start for the reception and distribution of air-borne casualties to three aerodromes in the neighbourhood of Swindon. The general scheme for the reception and treatment of these was similar to that for sea-borne casualties, with hospitals corresponding to port hospitals for those unfit to travel. The remainder of the casualties were transported to home base hospitals direct by train, no intermediate use being made of transit hospitals as casualty clearing stations. With the collapse of Germany Service patients of another kind came under the care of the E.M.S.—liberated British prisoners of war, together with numbers of civilians released from enemy hands. Most of them were evacuated from the Continent in the same way as battle casualties, but many were sent to hospital from the reception camps, where they were found to be in need of hospital treatment. Special forms of care were needed owing to malnutrition and other results of prison life.

Never before had the voluntary and municipal hospitals been welded together into an organic whole, working together under the regional and central direction of medical officers of the Government while preserving the internal autonomy of each hospital and the clinical freedom of the medical staff. Never before had the leading medical and surgical specialists placed themselves at the disposal of an organized medical service, and, by their dispersal up and down the hospitals of the country, spread their special knowledge among the medical profession as a whole to the benefit of the civilian population in general. Never before had it been possible on a national scale to separate out the patients requiring special treatment for special conditions—head injuries, facial injuries and burns, neuroses, and so on—and to send them to centres set apart for them, where the most skilled staff and the best equipment were available.

The Debate

Mr. James Griffiths spoke of sanatorium and hospital treatment in Wales. The Welsh National Memorial Association was concerned about the plight of Service and ex-Service men: there were some 450 of these occupying beds in the association's sanatoria and 157 others were on the waiting-list. In South Wales there were 2,000 persons waiting to go before the medical board for certification of silicosis. Of the negotiations on the White Paper he said it was clear that there had been fundamental departures from the principles of that Paper. This was not negotiation: it was capitulation; the Minister had given in to the B.M.A.

Mr. Willink intervened to say that he had engaged in discussions but had not sought binding agreements. It was for Parliament to decide what the form of the service should be.

Mr. Griffiths said there had been a betrayal of the House. The B.M.A., in a circular to its members, "welcomed certain fundamental changes in the Government's proposals." The Minister had submitted to those who met him proposals fundamentally different from the scheme already submitted to the House. Was the Government promising one thing in its manifesto to the country and another to the B.M.A.? Did the present Government stand by the White Paper submitted by the last Government? Was it true that fundamentally different proposals had been submitted to the B.M.A. with an assurance that if the members accepted them the Ministry of Health would press them on the Government? Those proposals meant that there would be no comprehensive National Health Service, but only a botched-up panel system.

Sir John Boyd Orr said that during the war, in spite of the scarcity of food, while the wealthy classes had got less than before they had not suffered in health; and the diet of the poorer classes had been levelled up. Increased consumption of protective foods and the change from white bread to bread with 85% extraction flour had led to a great improvement in the health value of the diet. Proteins, calcium, phosphorus, iron, and all the vitamins, with the possible exception of vitamin C, had increased in the diet of the working class from 10% to 40%. It would take some years before all the results were worked out, but there had been a definite improvement in the health and physique of the working classes. The infant mortality rate was also influenced by the feeding. If the level of housing and of feeding were brought up to well-known health standards and there was a sense of social security, more than 50% of the disease which afflicted the working classes could be prevented. Ten years would be added to the expectation of life of children born in those classes.

Health Service Negotiations

Dr. Edith Summerskill referred to "the document which had been circulated in the country embodying the proposals made by Mr. Willink to the B.M.A." She asked the Minister whether he had agreed to drop the introduction of health centres throughout the country. She understood they were to be dropped, although a majority of doctors in reply to the questionary from the B.M.A. had supported them. It was clear that the Minister and his friends were not happy at having this betrayal ventilated before the election. She had hoped that in the health centres the general practitioners would come together and would gradually achieve a much higher standard of medical practice. Now the Minister suggested that the general practitioner should remain isolated. The White Paper had suggested that voluntary hospitals and the municipal hospitals should be administered by one board. That had gone; the voluntary hospitals and their associations were to remain. The new proposals were designed to give the cottage hospital a new life while continuing to deny it adequate staff. The general practitioner would still be allowed to undertake major operations. The White Paper proposed that newly qualified doctors should be sent to practise in parts of the country where there was a dearth of doctors.

Mr. Willink intervened to say that the White Paper did not propose a power to direct a young doctor anywhere.

Dr. Summerskill said the Minister's alternative which was put to the B.M.A. read: "The proposed requirement that all doctors proposing to enter practice in new areas must obtain the Board's consent would be dropped." This meant in effect that the privileged would be assured of medical treatment while the worker might have to sit for an hour or two in a surgery before he received attention. To-day one-third of the doctors of the country were in the Services. What was to happen to the young doctor when he returned? The only freedom the Minister was giving him was freedom to go to the moneylender when he came back from the Services.

Mr. Storey said Mr. Griffiths and Dr. Summerskill had made an unfair attack. The Minister had not dropped proposals which had been approved by the House. The discussions with the B.M.A., the B.H.A., and the local authorities were on alternative proposals which the Minister said he would put before his colleagues only if they were agreed by the bodies concerned.

Dr. Morgan said he was a member of the Council of the B.M.A. and was astonished at the antimedical feeling in some quarters because the recognized organization of the doctors had desired to negotiate with the Government and with other bodies to discuss the conditions of their work in future. It was no secret that the B.M.A. had entered into discussions with the Trade Union Congress. As a result of the Llanelly medical dispute a joint committee was formed between the B.M.A. and the T.U.C. which discussed problems interesting to both. He himself had objected to certain terms of the White Paper which he thought involved the directing of young doctors. The Minister had given him personal assurance that it was not the intention of the Government to direct doctors into particular areas. What principles had been broken in the discussions? Uniformity was still there, availability was still there, necessity for the fully trained competence of the doctor was still there, adequate planning was still there, prevention was still there. Unfortunately in regard to the administrative structure the Minister had allowed the medical profession to put forward proposals which would give the profession a majority in most of the bodies. The consultants in voluntary hospitals had seen to it that they got a big share in any proposed administrative system. He thought, however, that if negotiations were allowed to continue things would right themselves.

Mr. Willink said the projected Bill was not, as had been hoped, being introduced in the course of this Parliament. It would be introduced in the new Parliament. No Government constituted as the present one would in any way limit the availability of the proposed service or its comprehensive character, nor would they fail in achieving any of the objectives of the White Paper. It was not for the Government to square its declaration of policy with a document issued by the B.M.A. The declaration of policy would be found in the Prime Minister's declaration issued the previous day. No agreements of any kind had been made with the bodies which undertook the discussions.

Dr. Haden Guest suggested that if the medical men in the Services had not been adequately consulted special steps ought to be taken to do so. A large number of the doctors serving in the Army strongly favoured the White Paper in its original form with some modification in the direction of more fully representing the State medical service proposals. The doctors in the Services deserved special attention because much more progress had been made in medicine and in surgery in the Army than in civil life. If doctors were to have to buy their practices in the future what was to become of the recommendation of the Goodenough report that a larger proportion of doctors should be recruited from the working classes? At present only 6% of the doctors came from those classes.

Dr. Russell Thomas said it had become clearer to hospitals, the medical profession, the public, and probably to the Minister and the Government that the principles of the White Paper could not be enforced because the public would not swallow the bringing into office of the types of officials envisaged.

Nursing and Tuberculosis

Mr. Sorensen asked on May 31 about the conditions of nurses in tuberculosis sanatoria.

Mr. Willink said that with the Minister of Labour and National Service he had under consideration the conditions in a number of sanatoria. Many were satisfactory; others had defects that could be remedied only by building that could not at present be undertaken. Others were in isolated situations so that the provision of certain amenities was difficult. Such steps as were practicable in present circumstances were being taken to remedy these defects. There was no prescribed minimum age either for tuberculosis nursing or for other types of nursing. It was preferable that girls undertaking nursing should not be under 18. The Athlone Committee, which reported in 1938, considered that 17 should be the minimum age. Statistics on the incidence of tuberculosis among sanatorium nurses were not available. The general opinion of experts was that the sanatorium nurse was at no greater risk than other nurses. An inquiry was in progress under the Joint Tuberculosis Council. Mr. Willink added that in March, 1944, he had issued a circular on precautions advised to safeguard nurses in hospitals.

Mr. Sorensen said a number of medical experts, including medical officers of health, declared that younger nurses were more prone to catch this disease than were the older ones. Mr. Willink said the inquiry would take account of that.

Tuberculosis Waiting Lists

Mr. HAMMERSLEY asked on May 31 whether steps could be taken to deal with the tuberculosis patients in Middlesex whose treatment was delayed owing to insufficient hospital accommodation. Mr. WILLINK answered that this problem, which was not confined to Middlesex, received his constant attention. He was taking all possible steps, in collaboration with the Minister of Labour and National Service, to ease the situation, but great difficulties were caused by the present demands on building labour and material and the dearth of nursing and domestic staff. He could not promise that the amelioration would be rapid. He would look into the possibility of using hospitals which the Americans had evacuated and had turned over to British military authorities.

Malaria and Quinine Supplies

Mr. AMERY said on May 31 that it was not possible to give reliable figures of deaths in India specifically attributable to malaria nor to estimate to what extent they might have been reduced by greater use of quinine. The supply of quinine until the Japanese occupation of Java was broadly equal to the demand. Supplies of synthetic substitutes had for some time been reaching India in substantial quantities. Of the 244,000 lb. of quinine in stock in April, 1944, 200,000 lb. was available for civilian consumption.

Medical Man-power and the Education Act

Mr. STOREY on June 7 asked the Minister of Education whether he was aware of the difficulty of local education authorities, owing to the shortage of doctors and nurses, in carrying out the duties imposed on them by Section 48 (3) of the Education Act, and what steps he proposed to prevent authorities from throwing further burdens upon the depleted medical personnel of the country.

Mr. RICHARD LAW in reply said he was aware of the shortage of doctors, dentists, and nurses and of the strain under which they were working. In Circular 29 authorities had been asked to extend their arrangements with hospitals so as to secure free hospital treatment for all children attending maintained schools, so far as accommodation and staffing conditions allowed, and to develop those clinic services which had always been recognized as appropriate to the school medical service. The needs of urban areas generally would be met in this way. The position in rural areas was more difficult, and the circular suggested that authorities should arrange for the treatment of children where necessary by local general practitioners. Such arrangements could be made only on a limited scale, but it was hoped that here and there doctors would be found who were willing to undertake this work in a part-time capacity under arrangements made by the authorities and approved by his Department. An assurance was given in the House during the third reading of the Education Bill that the development of the school medical service would not be inconsistent with, or duplicate provision to be made by, the National Health Service of the future. He would not approve any proposals leading to the setting up by local education authorities of a general medical practitioner service. The Act had been passed and its provision must, so far as practicable, be implemented. The service which could be provided in the next year or so must be limited to the extent necessary to comply with the undertaking given about its relationship with the future National Health Service. The scope of the service must also be restricted owing to the shortage of medical man-power.

Sheffield Silicosis Board's Work.—The Sheffield Panel of the Silicosis Medical Board, under all the compensation schemes for pneumoconiosis, including silicosis and asbestosis, dealt in the year 1944 with 298 applications and granted 112 certificates. In 1943 the comparable figures were 159 and 51; in 1942, 74 and 19.

Refusal of Drugs in the Army.—Mr. VIANT on May 29 asked whether officers or other ranks, who had a strong objection to taking drugs such as mepacrine, had a right to refuse. Sir JAMES GRIGG said they had not. Officers and other ranks had no right to refuse to obey a lawful order. Commanders-in-Chief were entitled to issue orders to ensure that their troops were fighting fit and kept free from disease. Neither religious scruples, however bona fide, nor dislike of unpleasant after-effects, afforded justification for refusing to take mepacrine.

Harley Street Houses.—Mr. CHURCHILL told Sir Ernest Graham-Little on May 31 that the majority of the houses requisitioned in the Harley Street area by Government Departments were used to house American officers, as offices for French missions and branches of the French Embassy, or as hostels. The possibility of reducing the number retained was being examined with occupying authorities. Any houses which could be vacated would be released. Five requisitioned houses now vacant were being released immediately. Sir ERNEST in his question reported that 56 houses in the area continued to be requisitioned. He said evidence had been submitted to Mr. Churchill of a shortage in this area of houses for medical consultants.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The Registrary has given preliminary notice that Monday, June 25, will be nomination day for the University Parliamentary Election. Polling days for ordinary electors and for all proxy voters will be from Thursday, July 5, to Tuesday, July 10 inclusive (but not on Sunday, July 8). Service postal votes may be received not later than July 29. The count will begin on July 30 and the result be declared by July 31.

At a Congregation held on June 8 the following medical degrees were conferred by proxy:

M.B., B.CHIR.—R. D. Hearn, J. M. Davis.

UNIVERSITY OF SHEFFIELD

The University Council on June 8 received with regret the resignation of Mr. Vincent Townrow, F.R.C.S., of the post of lecturer in diseases of the ear and accorded him its thanks for his services to the University. G. L. Hermitte, M.B., Ch.B., was appointed temporary demonstrator in anatomy.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

At a meeting of the Royal Faculty of Physicians and Surgeons of Glasgow held on June 4, with Mr. Wm. A. Sewell, President, in the chair, Sir Alfred Edward Webb-Johnson, Bt., K.C.V.O., C.B.E., D.S.O., President of the Royal College of Surgeons of England, was admitted an Honorary Fellow.

Medical News

During his recent tour in Sweden to lecture on penicillin, under the auspices of the British Council and at the invitation of the Swedish Medical Society, Sir Howard Florey, F.R.S., was honoured with the presentation of the Berzelius Medal in Silver. This medal was presented to members of the Swedish Royal Family and certain other distinguished persons when it was instituted in 1850. It had not been awarded since that time.

The annual general meeting of the Paddington Medical Society will be held at the Paddington Tuberculosis Dispensary, 14, Newton Road, W., on Tuesday, June 26, at 9 p.m., when the president, Dr. Z. Green, will speak on "War Experiences in General Practice."

The next science meeting of the Physical Society will be held at 5 p.m. on Friday, June 29, at the Royal Institution, Albemarle Street, when the 14th Thomas Young Oration will be delivered by Prof. Ragnar Granit, of the Nobel Institute for Neurophysiology, Stockholm, his subject being "The Electrophysiological Analysis of the Fundamental Problem of Colour Reception."

The following sessional meetings of the Royal Sanitary Institute are announced: Saturday, June 30, 10.15 a.m., at Sunderland Town Hall, papers on "The Water Supply in the County of Durham" by Messrs. A. B. E. Blackburn, J. A. Rodwell, and W. G. Carey; Saturday, July 7, at 10.15 a.m., at Banbury Town Hall, papers by Prof. G. Selby Wilson, "Bacterial Food Poisoning," and by Mr. J. Campbell Riddell, "Survey of Sewage Treatment and Sewage Treatment Works Design."

A meeting of the Medical Society of the L.C.C. Service will be held at St. Andrew's Hospital, Devons Road, Bow, E., on Thursday, July 5, at 3 p.m., when members of the staffs of Mile End, St. George-in-the-East, and St. Andrew's Hospitals will demonstrate cases.

The Trustees of the Lady Tata Memorial Fund announce that, on the recommendation of the Scientific Advisory Committee, they have agreed to make the following awards for research in blood diseases, with special reference to leukaemia, in the academic year beginning Oct. 1, 1945. *Grants for Research Expenses:* Dr. P. A. Gorer (London), Dr. A. H. T. Robb-Smith (Oxford). *Personal Grant:* Dr. Penelope K. Hammick (Oxford). *Part-time Personal Grant and Grant for Research Expenses:* Dr. W. Jacobson (Cambridge). Since these awards do not fully use the margin of funds available, it is hoped to issue a public advertisement for new candidates from the continent of Europe and elsewhere as soon as conditions permit.

Major R. Scott Stevenson, M.D., F.R.C.S.Ed., has been adopted as Liberal National candidate for Western Fife at the General Election.

A party of scientists left England on June 14 for Russia to attend the celebration of the 220th anniversary of the founding of the Academy of Sciences of the U.S.S.R. The medical members were Prof. E. D. Adrian, O.M., F.R.S. (who represented the University of Cambridge) and Prof. Arnold Sorsby, F.R.C.S. (representing the Anglo-Soviet Medical Council). The party arrived in Moscow on June 15.

No. 22

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended June 2.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week the incidence of whooping-cough rose by 127 cases, that of dysentery by 84, and that of diphtheria by 40, while falls were recorded for measles and scarlet fever of 953 and 62 cases respectively.

Small increases in whooping-cough were recorded in many counties; the largest were Lancashire 29, and Yorks West Riding 27. The biggest increases in diphtheria were Kent 14, and Derbyshire 13. The trend of scarlet fever showed only small variations, the largest of which were a rise in Lancashire of 28, and a fall in Warwickshire of 29. The largest declines in measles were Yorks West Riding 245; Glamorganshire 166, Middlesex 139, Devonshire 110, London 106; and the chief exceptions to the general decline in incidence were rises in Monmouthshire 111, Essex 101, Hertfordshire 55.

The increase in dysentery was due to a large outbreak in Berkshire, where the cases rose from 8 to 106. The centre of infection was Windsor R.D. 75, and Easthampstead R.D. 27. Other large returns were Lancashire 50, London 37, Surrey 30, Middlesex 24, Kent 22, Essex 22, Yorks West Riding 16, Warwickshire 12, Shropshire 11, Bedfordshire 10, Gloucestershire 10.

In *Scotland* rises occurred in whooping-cough 53, dysentery 48, measles 25; while diphtheria decreased by 26. The increase in dysentery was mainly contributed by a rise in the city of Aberdeen from 13 to 30, and by an outbreak of 17 in Moray, Nairn County; other large returns were those of the cities of Glasgow 38, and Edinburgh 20.

In *Eire* a rise of 35 in diphtheria formed the chief feature of the returns; the disease is widespread and the 108 notifications involved 38 registration areas. Diarrhoea and enteritis remained at a high level in Dublin C.B., where 30 more cases were recorded during the week.

Week Ending June 9

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,409, whooping-cough 1,033, diphtheria 423, measles 8,463, acute pneumonia 427, cerebrospinal fever 52, dysentery 426, paratyphoid 4, typhoid 6. Two cases of typhus were imported.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Pityriasis Versicolor

Q.—*A girl aged 24, in good general health, suffers from a rash on the trunk, inside of the thighs, the deltoid region, the front and lateral aspect of the arms, and the radial border of the forearm to the wrists. The buttocks, lateral sides of the thighs, axillae, triceps, and ulnar side of the forearms are normal. The rash is symmetrical and has a "jig-saw" edge. It was first noticed about twelve years ago, when the areas affected were mostly the back and shoulders. From here it spread gradually forward around the trunk until it has met along the midline on the abdomen and lower chest. The skin over the upper part of the chest and between the breasts is free except for small isolated patches. The rash is light brown and yellowish in colour over the upper part of the body and arms; over the abdomen it is darker. There is pityriasis capitis, and septic spots on chin and neck. There is a history of a similar but milder condition in the patient's father. What are the probable diagnosis and the most effective treatment?*

A.—The description suggests pityriasis versicolor. The diagnosis can be verified by examining scales for the causal fungus (*Microsporon furfur*). If this diagnosis is confirmed treatment with 3% benzoic and salicylic acid in vaseline should be effective, a portion of the eruption being treated at a time. Suitable disinfection of clothing prevents reinfection.

Fractures and Urinary Calculi

Q.—*I have been impressed by the number of war casualties laid up with compound fractures that get calculi in the renal tract. What is the cause of this, and how may it be prevented?*

A.—The special factors in the formation of recumbency urinary calculi are decalcification of bone and urinary stasis. Generalized decalcification has been explained on the basis of relative hyperaemia of bone, the result of muscular inactivity. In addition to this, with compound fractures large amounts of calcium may be mobilized locally through inflammatory hyperaemia. Thus the blood calcium is raised, leading in turn to a raised urinary calcium, a major factor in stone formation. Urinary stasis is the result of long-continued decubitus. It is obvious that in this position any solid particles must tend to be deposited in the renal calices and pelves, and to remain there, forming the nuclei of future stories; this effect will be increased when the foot of the bed is raised, as in the traction treatment of certain lower-limb fractures.

The most important general factors probably are an alkaline reaction and a high concentration of the urine. The commonest recumbency stone is composed chiefly of calcium phosphate, which is precipitated only in an alkaline urine. The reaction is influenced by diet and drugs and also by infection. High concentration is chiefly caused by low fluid intake, but prolonged exposure of the body to the hot sun may have the same effect through excessive perspiration. Among other aetiological factors may be mentioned vitamins A and D; there is a fair amount of evidence that excess of vitamin D or deficiency of vitamin A may cause stone formation.

Much can be done to prevent this complication, and the chief methods of prevention will be apparent from what has been said. Disuse decalcification can be minimized by encouraging active movements of the uninjured parts. To facilitate urinary drainage the patient's position should when possible be changed at regular intervals by turning him on to his side or into the prone position, and by raising the head-end of the bed on blocks. Plenty of fluids should be given and excessive exposure to the sun avoided. The urine, if alkaline, should be made acid by diet and possibly by drugs; the latter should rarely be necessary with an uninfected urine unless calculus is actually present. Finally, there is sufficient evidence to justify the use of vitamin A as a prophylactic, and the possible danger of vitamin D should be remembered.

Calcification and Cancer

Q.—*Calcification is one method of cure in tuberculosis. Is there any reason to expect that if calcification could be induced in a cancer, delay or arrest of growth might occur? It is common in cerebral tumours which are slow-growing. I have seen it in a hypernephroma which "galloped" to its end.*

A.—There seems to be no reason to expect a cure for cancer from calcification, a pathological process which often occurs when dead tissue is retained in the body. Presumably the tumour cells would have to be killed antecedent to the calcification, and if all the tumour cells were killed the cure would be complete before deposition of lime salts began. When tumours regress, as they often do in transplanted growths, calcification does not occur, and there is no substantial evidence warranting a belief that it would occur in human tumours which have been partly destroyed. Moreover, in meningiomas, in which calcium salts are so frequently deposited, cures are not observed as a consequence of the process. Of course cells may be involved and killed in calcification, but it is very unlikely that this common process can be started and controlled effectively and used to cure cancer. The trouble with cancer cells is their ability to grow and divide, not to die.

Inheritance of Epilepsy

Q.—*Miss A. wishes to marry Mr. B. She learns that his mother died in an epileptic fit. Of Mr. B.'s brothers, one is mentally deficient, and the other is described as being abnormally moody. Mr. B. himself is described as mentally normal. Miss A. wishes to know her chances of producing normal children.*

A.—The facts provided are insufficient to allow a precise answer to the question. Further points on which information would be desired are: (1) Was the mother an epileptic, or was the epileptic fit merely a terminal manifestation? (2) What degree of mental deficiency does the brother show, and of what clinical type is it—e.g., could it be due to birth injury or other external conditions? (3) If electro-encephalographic tests could be carried out, does the moody brother and does Mr. B. himself show cerebral dysrhythmia? (4) Is there any evidence of instability of any kind in Miss A.'s family, and is Miss A. herself perfectly normal?

If both Miss A. and Mr. B. are themselves perfectly normal and are over the age of 30 (by which time tendencies to instability might be expected to have shown themselves), the outlook for their children is quite good regardless of the bad family history on one side. If it can be fairly easily arranged it would be desirable for both to have an electro-encephalographic examination. The chance of epileptic or otherwise abnormal children is material if both, despite apparent normality, were to prove to have cerebral dysrhythmia.

Drugs causing Bronchodilatation

Q.—*Is there any drug that may be successfully used to cause bronchodilatation without affecting the heart, and if so what is the dose, how often should it be used, and are there any contraindications in asthma?*

A.—There is no drug which causes dilatation of the bronchioles without having some effect, however slight, on the heart at the same time. For practical purposes, the only useful drugs for causing bronchodilatation are adrenaline, ephedrine, and theophylline (or substances related to it). Adrenaline is well known to cause increased force and rate of heart-beat and is disagreeable to some patients for this reason. Ephedrine has a similar, though much less violent, action on the heart, and when used in the correct dose (which differs from one patient to another) should have very little cardiac effect. By reducing the rate at which the patient's own adrenaline is destroyed it maintains vasodilatation in the bronchioles. Theophylline with ethylene diamine, given intravenously, is found by some to be of value in the most severe asthmatic attacks which are not relieved by the injection of adrenaline. Theophylline causes a dilatation of the coronary vessels and slight augmentation of the force of the heart-beat, but this effect on the heart is rarely evident even to the patient.

Treatment of Smallpox

Q.—*Have there been any recent advances in the treatment of smallpox? Is there any "serum" therapy such as convalescent serum or the serum of successfully vaccinated persons? Does penicillin materially affect the course of the disease apart from preventing secondary infection? What is the best treatment for the actual skin condition?*

A.—The treatment of smallpox remains essentially symptomatic. Sulphonamides and penicillin probably exert an indirect influence by attacking the secondary invaders, but that is all. Convalescent smallpox serum was used over 20 years ago and subsequently discarded. However, recent methods of concentrating antibodies in human globulin appear to justify reassessment of the value of convalescent serum in the treatment of a number of diseases. Of the various local applications tried on the skin lesions, the one which has found most favour is a saturated solution of permanganate. This antiseptic inhibits the growth of the smallpox virus and appears of established value when applied early—i.e., in the papular stage.

Viability of Disease Organisms

Q.—*What are the viabilities of the causal organisms discharged from the body during the course of the following communicable diseases under the conditions of temperature, moisture, etc. (but not antisepsis) to which they are exposed in the average sick-room? (a) Cerebrospinal fever; (b) diphtheria; (c) gonorrhoea; (d) syphilis; (e) pneumococcal pneumonia; (f) scarlet fever; (g) whooping-cough; (h) pulmonary tuberculosis; (i) non-pulmonary tuberculosis; (j) acute encephalitis lethargica; (k) measles; (l) influenza; (m) chicken-pox; (n) smallpox; (o) mumps; (p) poliomyelitis.*

A.—The viability of pathogenic bacteria and viruses in natural discharges under the ordinary conditions of temperature, humidity, etc., in a sick-room or hospital ward is not easily determined, and will vary with dosage, degree of protection by mucus or dust, exposure to daylight, rate of drying, etc. However, it has been found that under such natural conditions pneumococci will remain viable for some days, and haemolytic streptococci and diphtheria bacilli for some weeks, in the dust of ward or sick-room. The tubercle bacillus is very susceptible to the bactericidal action of light—and daylight even through glass is bactericidal—so that exposure in a room for a few hours is lethal unless dosage is heavy. Tubercle bacilli in discharges from suppurative lesions of non-pulmonary tuberculosis will be similarly affected. The Gram-negative diplococci, meningococcus and gonococcus, and *Treponema pallidum* die within a few hours in drying secretions, but may remain alive for 24 hours or longer if the discharges remain moist. (*Treponema pallidum* from the serous exudate of a chancre has crossed the Atlantic 4 or 5 times in a sealed capillary tube and still remained motile.) Little is known about the viability of the pertussis bacillus, but the fact that the transmission of whooping-cough usually requires intimate contact suggests that the infecting organism is not very resistant to environmental influences.

Among the virus diseases listed, nothing seems to be known about the viability outside the body of the causative agents of measles, mumps, encephalitis, and chicken-pox. Influenza virus, after being atomized into the air in concentrated suspension, remains infective to mice for 6 hours in a relative humidity of 45 to 50%, and for longer periods in a drier atmosphere. The virus of smallpox seems to be particularly resistant to desiccation if we accept reports of infection being conveyed in bales of cotton from Egypt to this country. As regards poliomyelitis, there is considerable controversy as to how the infection is spread: it has not apparently been recovered from the environment of an infected case, but it is recoverable from the sewage effluent of a hospital where patients with poliomyelitis are being nursed.

Mirror-writing

Q.—*A healthy, intelligent, left-handed girl of 6½ indulges in mirror-writing. Is any treatment necessary, apart from education by her school teachers? She is the elder of two girls, and appears to be jealous of attentions paid to her sister (aged 2).*

A.—One would like to know whether the mirror-writing is carried out habitually or only on occasions. (It is assumed that the writing is being done with the left hand.) If the mirror-writing is merely an occasional event, then no action is called for. The phenomenon should be ignored and not encouraged.

Should, however, the mirror-writing be the regular practice, then two ways lie open: either to change over and use the right hand, or else to force the left hand to write in the proper fashion. This latter is none too easy, for mirror-writing represents the most natural way of writing with the left hand. To change from left-handed to right-handed penmanship is not very desirable, and the traditional belief that stammering is thereby produced is not altogether fallacious. On the whole, the most desirable procedure would be for the teacher to insist upon the child correcting its mirror tendencies, but continuing to use the left hand.

Xerostomia and Aptyalism

Q.—*A woman of 70 has suffered since the early raids on London from more or less complete absence of saliva. Her tongue is red and glazed and somewhat fissured, the tip at present having a painful crack. Mastication is difficult. Many people know how dry the mouth becomes during moments of fear, but that this woman's should have continued in this state is unusual. Is it likely to be a hysterical prolongation of a condition which had at first a physiological basis; or is the pathology perhaps due to something else entirely?*

A.—Little is known of the pathology of xerostomia and aptyalism. Dry mouth is sometimes associated with similar symptoms in other systems—keratoconjunctivitis sicca, achlorhydria, anaemia, arthritis, etc.: the so-called Sjögren's syndrome. The condition occurs characteristically in middle-aged and elderly females. The aetiology has been variously ascribed to neurosis, avitaminosis, and infection, but it seems unlikely to be a hysterical perpetuation of a fright reaction. No specific treatment is known, though removal of dental infection and the use of cod-liver oil have been recommended.

Flush Ligature for Varicose Veins

Q.—*In a woman of 30 both lower legs show small varicose veins which have been injected during the past five years with sodium morrhuate, quinine and urethane, etc. By annual attention the lower legs can be kept free but not cured. In both upper legs the saphenous vein shows up as a prominent straight vein running from the internal aspect of the knee and fading into the upper thigh. The characteristic tortuous appearance is not present except at the beginning at knee level. No cough impulse. Repeated injections have failed to cause thrombosis, and the patient is anxious to have the vein rendered invisible. Is there any method other than ligation at the groin which will do this?*

A.—This case would be best treated with a flush ligature in the groin so as to separate the saphenous vein and its inguinal tributaries from the femoral vein. A second ligature just above the knee would also help. At the time of the ligatures the distal vein when exposed in the wound should be injected with a sclerosing agent, and after two weeks' interval the remaining patent veins should be injected systematically. A long-standing cure should be obtained in this way, and the ligatures done under local analgesia with no recumbency afterwards are not a great inconvenience.

Hypomenorrhoea

Q.—*A married woman aged 35 has for the past two years suffered from hypomenorrhoea. Whereas the menstrual flow lasted four to five days, it now lasts one day only and is scanty. There has been no alteration in rhythm. The only other symptom is undue fatigability. This is not an isolated case in my experience, and I find that the women themselves attribute it to general anxiety engendered by the war. Is there a possible endocrinological basis, and is any treatment indicated?*

A.—Unlike the cause of menstruation, the factors which determine the amount and duration of the menstrual flow are largely unknown. Those possibly of importance are the strength of the hormone stimulus, the ability of the uterine tissues to respond to the stimulus, anatomical variations in the vascular system of the endometrium, the action of the muscles of the myometrium and the blood vessels, and the area of the bleeding surface (i.e., size of the uterus). Clinical experience goes to show, however, that scanty menstruation is often of little, if any, significance. On the other hand, hypomenorrhoea, like amenorrhoea, can result from any general disturbance or ill-health—including malnutrition, prolonged nervous strain, etc. The conditions created by the war might well be responsible for altering the character of the menstrual flow in some cases. The tendency to fatigue, however, is not likely to be due to the scanty menses, but rather to the same environmental causes. Although it is supposed that there is some depression of pituitary or ovarian function (arising either directly or indirectly via the hypothalamus) in these cases, there is no indication for replacement therapy with hormones. Treatment should be directed to the cause, and efforts made to ensure that the patient has a proper diet, adequate rest and leisure, freedom from anxieties, and change from the daily routine.

Kahn Verification Test

Q.—*I have read your two notes on the positive Kahn in yaws (*JOURNAL, *March 31, p. 469, and April 14, p. 543). What is the Kahn verification test? Does it enable one to distinguish between the true and false positive serological reactions for syphilis? Does it enable one to distinguish between syphilis, yaws, and other conditions that give the so-called "false positive"? Please give either details of the technique of the Kahn verification test or else references.*

A.—The Kahn verification test is not a diagnostic test but a supplementary test. If the diagnostic test is positive the verification test is supposed to indicate whether the positive reaction is associated with syphilis or not. While this may be the case where false positive Kahn reactions are encountered in such conditions as malaria, leprosy, or typhus, it seems unlikely to hold in the case of such a closely similar condition to syphilis as yaws, although information on this matter is scanty. There is considerable literature on the Kahn verification dating from 1940, as follows:

LETTERS, NOTES, ETC.

Civilian Jobs for Medical "Other Ranks"

Lieut.-Col. J. G. FOSTER writes from 85, Eccleston Square, London, S.W.1: In reply to the letter of Dr. J. McD. Glennie (June 9, p. 824), may I bring to notice the Royal Army Medical Corps Association? This organization up to the outbreak of war did invaluable service in finding work for other ranks of the R.A.M.C. on discharge, and we hope now that the war is over and men become available to resume our activities. Every man on discharge is handed a slip with our address. On this he shows his qualifications and the kind of work he desires.

Dr. P. H. KENDALL (Stoke-on-Trent) writes: I would like to ask the following question. The letter on civilian jobs for medical "other ranks" includes the question: "Can we offer them reasonable employment at reasonable wages?" What help might one expect from a first-class nursing orderly for dressings, massage, injections, dispensing, assistance at minor operations, and medical clerical work, and what reasonable wage should one offer?

Correction

In the account of the discussion at the Royal Society of Medicine on the physiology and treatment of starvation, in the *Journal* of June 9 (p. 818), Dr. P. Cuthbertson was wrongly reported at the end of the third paragraph under the heading, "Preparation of Hydrolysates": ". . . providing 50 grammes of hydrolysate and 50 grammes of glucose" should have read ". . . 50 grammes of hydrolysate and 150 grammes of glucose per day."

PENICILLIN THERAPY IN ACUTE BACTERIAL ENDOCARDITIS

BY

A. DOLPHIN, M.D., D.P.H., B.Sc.
Senior Medical Officer

AND

R. CRUICKSHANK, M.D., M.R.C.P.
Pathologist

(From the L.C.C. North-Western Hospital and Group Laboratory, Hampstead)

isease of the heart valves caused by bacteria which can be covered from the peripheral blood is generally divided into ute or ulcerative and subacute endocarditis. Acute bacterial docarditis is usually caused by pyogenic cocci—haemolytic eptococcus, *Staphylococcus aureus,* and the pneumococcus. *reptococcus viridans* is the causal organism in most cases subacute bacterial endocarditis, but other non-haemolytic eptococci, *H. influenzae,* diphtheroid organisms, etc., may be ncerned. The illness in the first group usually has the atures of a septicaemia, with the endocarditis developing ring the course of a generalized infection, and it terminates tally within a few days or weeks. In subacute bacterial endo-rditis, which usually has an insidious onset, the illness is aracterized by low-grade fever, embolic manifestations, and ogressive anaemia, and it runs a course of many weeks months before death occurs. The results of sulphonamide erapy in both kinds of the disease have been disappointing. nicillin is now on trial, and this paper reports the good effect the drug on six patients who had the acute form of the ness. In most cases clear-cut evidence of endocarditis veloped after treatment with penicillin had been started for septicaemia that had not responded to sulphonamides. Before scribing our own cases we propose to give a brief review of rlier reports on the treatment of acute and subacute bacterial docarditis with sulphonamides and penicillin.

Sulphonamide Therapy

Reports have appeared of cure of *Str. viridans* endocarditis sulphonamides, but Willius (1942) has stated that careful alysis of the data presented about many of the cases casts stifiable suspicion on the diagnosis. Thus the presence of ver, a cardiac murmur, and a positive blood culture have often en the grounds for the diagnosis of bacterial endocarditis, though other essential signs, such as emboli, splenomegaly, aemia, and progressive wasting, have been lacking. In many ses the follow-up period has been too short to justify the ims of cure, and, unfortunately, authors have subsequently iled to correct premature conclusions. Katz and Elek (1944) om their own experience and the reports of others concluded at sulphonamides, combined with heparin, were ineffective in treatment of *Str. viridans* endocarditis.

In acute endocarditis a study of the reported cases does not ggest that sulphonamide therapy has been effective. The glish literature of the past ten years records 14 cases of acute docarditis due to haemolytic streptococci other than Lance-ld Group A (9 Group B, 1 Group C, and 4 Group G); in ite of sulphonamide therapy, given in massive doses in 8 ses, all the patients died. Colebrook and Purdie (1937) in a ries of streptococcal puerperal infections encountered one case Group B endocarditis and 2 cases of Group B septicaemia; three patients died. According to Fry (1938) Group B eptococcal septicaemia complicating post-abortum and post-rtum puerperal sepsis is particularly apt to lead to endo-rditis. He reported 2 fatal cases of Group B streptococcus docarditis which occurred in the puerperium. MacDonald 39) reported 2 fatal cases of Group G streptococcus endo-ditis. Hill and Butler (1940) in a series of 12 Group B eptococcus puerperal infections had 2 patients with bacterial endocarditis, both of whom died in spite of sulphonamide therapy. Rosenthal and Stone (1940) gave an account of 2 fatal cases of haemolytic streptococcal endocarditis—one due to Group C and the other to Group B. The Group C infection was treated with 79 g. and the Group B with 162 g. of sulphanilamide without obvious effect. Koletsky (1941) reported a case of Group B streptococcal puerperal endocarditis in which treatment with sulphonamides and numerous blood transfusions failed; death occurred three weeks after delivery. Ramsay and Gillespie (1941), in a series of 16 Group B streptococcal puerperal infections, described 2 patients who had septicaemia and bacterial endocarditis; both died in spite of massive sulphonamide therapy. Among 12 Group G cases there was one patient whose blood culture was positive and who died from bacterial endocarditis although treated with massive doses of sulphonamides. Kehr and Adelman (1942) unsuccessfully treated with 38 g. of sulphanilamide a Group A streptococcal endocarditis in a child aged 2. The drug had no effect on the course of the disease. Keith and Heilman (1943) reported a case of Group G streptococcal endocarditis in a girl aged 8 years with congenital heart disease. During three months in hospital, while on doses of sulphonamide sufficient to give a blood concentration of 14 mg. per 100 c.cm., cultures of her blood remained persistently positive. Cunliffe, Gillam, and Williams (1943) reported a fatal case of endocarditis due to *Staph. albus* (coagulase-positive). Sulphapyridine produced a fall in temperature but no clinical improvement.

The outstanding features in this review of recorded cases are the frequency of Group B streptococcus as a cause of acute endocarditis and the failure of sulphonamide therapy in both the acute and the subacute forms of the disease.

Penicillin Therapy

Florey and Florey (1943) treated a case of *Str. viridans* endocarditis with 4,760,000 units of penicillin over a period of 30 days. The patient appeared much improved at the end of treatment; but cultures of the blood three weeks later were positive, and after a further three weeks death ensued. Keefer and his associates (1943) treated with penicillin 17 patients who had subacute bacterial endocarditis. Four of them died, 10 were unaffected by the treatment, and 3 improved temporarily. The total dosages of penicillin varied from 240,000 to 1,760,000 units, given for periods ranging from 9 to 26 days. Better results were claimed by Loewe and his colleagues (1944), who used penicillin and heparin (given subcutaneously) in the treatment of 5 patients with subacute bacterial endocarditis; the patients were all well and their blood was still sterile several months after treatment ceased. A clinical trial on a larger scale has lately been reported by Dawson and Hunter (1945); 15 of the 20 treated patients with subacute bacterial endocarditis have been apparently cured of their infection by penicillin, with or without heparin: 12 of them have been in good health for periods of 5 to 22 months. These workers recommend a daily dosage of 200,000 units of penicillin for three weeks as the minimum standard treatment in subacute bacterial endocarditis.

There have been few reports of the effect of penicillin in acute bacterial endocarditis. Keefer and his colleagues (1943) treated 91 patients who had *Staph. aureus* bacteriaemia (quantitative blood cultures were apparently not done); of 34 fatal cases 9 had bacterial endocarditis, and none of them showed improvement during treatment. None of the recovered patients had bacterial endocarditis and no patient developed bacterial endocarditis after penicillin treatment had begun. Of 6 patients with primary pneumococcal endocarditis who were treated with penicillin 5 died and 1 recovered. Loewe *et al.* (1944) reported cures in one case of haemolytic streptococcus (group not stated) endocarditis and one case of pneumococcal endocarditis. Blood culture of the patient with haemolytic streptococcal endocarditis showed 130 organisms per plate (presumably per c.cm.) immediately before penicillin treatment was begun: 100,000 units of penicillin were given daily for 13 days. There was a dramatic response to the drug, but towards the end of the second week pulmonary oedema developed and digitalization was necessary. The patient with pneumococcal (Type 27) endocarditis was a girl aged 7½ years with congenital heart disease. She failed to respond to massive doses of sulphadiazine (blood concentration 74 mg. per 100 c.cm.), and repeated blood cultures were positive. During penicillin therapy numerous pulmonary infarcts developed, but she recovered sufficiently to return to school.

Thus the results of penicillin therapy in both acute and subacute bacterial endocarditis are encouraging enough to warrant further trial in these usually fatal infections. Penicillin has not hitherto been available for the treatment of subacute bacterial endocarditis in this country, but a co-operative trial is now being sponsored by the M.R.C. Penicillin Clinical Trials Committee (Christie, 1945).

Original Records

Six cases of acute bacterial endocarditis were treated in the puerperal sepsis unit at the North-Western Hospital and are a consecutive unselected series. Three of the infections were due to haemolytic streptococcus Group B, one was due to haemolytic streptococcus Group A, and two were due to *Staph. aureus.*

Case I

A multipara, aged 31, with no illness of note in the past history. Her present illness began after an abortion of three months' gestation, and when admitted to the unit she had been ill for one week, during which she had shivering attacks. Her general condition was good and she did not appear ill. The temperature was 99° F., pulse rate 80, and B.P. 110/70. The heart was normal except for a slightly "snappy" first sound at the apex, the lungs and C.N.S. were normal, and there were no local signs of genital tract sepsis. Cultures from the cervix and blood were sterile, the urine was normal, and a blood count showed R.B.C. 4,900,000, Hb 90%, and W.B.C. 12,000.

Five days later the temperature rose to 104° and blood culture showed haemolytic streptococcus Group B (3 organisms per c.cm.). Sulphanilamide was given (blood concentration, 9 mg. per 100 c.cm.), but after three days the drug was discontinued because of vomiting; sulphamezathine was substituted, 6 g. daily for six days. The temperature was normal during sulphonamide therapy except for a moderate rise on three occasions, but the pulse rate remained about 120. An apical systolic murmur appeared; at first faint, after a few days it became loud, rough, maximal at the apex, well conducted into the left axilla, and accompanied by a thrill. At the same time Osler's nodes appeared on the fingers, and the patient complained of pain like a "bruised" feeling in the left leg and foot. On examination the toes and distal half of the foot were deathly pale, and no pulsation could be felt in the left femoral, popliteal, and dorsalis pedis arteries. There was no splenomegaly, petechiae, or haematuria, the W.B.C. was 22,000, and quantitative blood culture showed 170 organisms per c.cm. The temperature was 99° F., but 24 hours later it rose to 101°. The patient was seen by Dr. Terence East, who confirmed the diagnosis of bacterial endocarditis. Penicillin treatment was begun. Except for the first three days, when an intravenous drip was used, the penicillin was given by intramuscular drip, using Eudrip No. 2 apparatus. Treatment was continued for 15 days. During the first seven days of therapy 100,000 units of penicillin were given daily (maximum blood penicillin level, 1:4), but as two blood cultures were positive during this period dosage was increased to 200,000 units daily for the remainder of the treatment, during which time blood cultures proved sterile. The total penicillin given was 2,300,000 units.

Twenty-four hours after treatment was begun the temperature fell to 98° F., and it remained normal afterwards except for an occasional rise to 99° during penicillin therapy. The general condition continued to improve; 12 negative blood cultures were obtained during the two months after treatment, and when the patient was discharged from hospital the sedimentation rate and W.B.C. had been normal for six weeks. There was a loud rough apical systoli murmur, accompanied by a thrill; radiographs of the heart wer normal, the patient felt in excellent health, and the left leg showe no disability, although there was diminished pulsation in the lef femoral artery.

Case II

A multipara, aged 42, with an old history of mitral stenosis. Sh developed puerperal sepsis after an abortion, and received 30 g. o sulphanilamide before her admission to the unit on the fourth da of pyrexia. She appeared ill, with temperature 100° F., B.P. 100/50 and had compensated mitral stenosis. There were no petechiae o Osler's nodes, no local signs of genital tract sepsis, and the abdomen lungs, and C.N.S. were normal. A blood count showed R.B.C 2,500,000, Hb 46%, and W.B.C. 7,000. Lancefield Group streptococcus was cultured from the cervix and quantitative bloo culture showed 35 haemolytic streptococci per c.cm.

Sulphamezathine, 6 g. daily, was given for five days, but th patient's general condition deteriorated; she sweated profusely, ha remittent fever up to 105° F., and the pulse rate averaged 140 Quantitative blood culture showed 127 organisms per c.cm. immediately before penicillin treatment was started on the ninth da of disease. Treatment continued for 11 days. During the first si days the drug was given by intramuscular drip, 100,000 units dail (blood penicillin level, 1:4), and afterwards by 6-hourly intramuscular injections of 15,000 units. The total penicillin given wa 960,000 units.

Twelve hours after penicillin treatment started the temperatur fell from 105° F. to 97°, remained normal for two days, and the rose to 102°, after which it fell by lysis. The general conditio improved, but on the third day of treatment a few petechia appeared on the neck Next day there was numbness and pain o sudden onset in the right foot; the toes and distal part of the foo became deathly pale, and no pulsation could be felt in the righ popliteal and dorsalis pedis arteries. Gangrene did not develop although pulsation could not be felt in the vessels for about si weeks. Since the patient's heart had not been fibrillating or i flutter it was considered improbable that the arterial obstructio was due to a thrombus arising in the left auricle. Five negativ blood cultures were obtained during penicillin therapy and fou negative blood cultures during the next two months. Five day after the penicillin was discontinued an intensely itchy generalize urticarial rash developed—probably an allergic reaction to the drug since other possible causes were eliminated. The temperature an sedimentation rate have been normal for four months, but convalescence has been slow because of a considerable reduction i her cardiac reserve. This was due to recent myocardial and endocardial damage superimposed on old heart disease.

Case III

A primipara, aged 27. The duration of her illness was not exactl known, but apparently she was ill for two days before admissio to the unit. Her general condition was then poor, she was drows and non-cooperative, the temperature was 101° F., and B.P. 110/7 There were no petechiae or Osler's nodes, and the lungs, abdomen and C.N.S., apart from the drowsiness, were normal. A bloo count showed R.B.C. 3,500,000, Hb 64%, and W.B.C. 19,000. Th uterus was slightly enlarged, but there were no definite signs o sepsis. Lancefield Group B streptococcus was cultured from th throat, cervix, and blood (quantitative blood culture showed 10 organisms per c.cm.). Sulphanilamide treatment was begun (bloo concentration, 9.5 mg. of free drug per 100 c.cm.), but blood cultur after two days' treatment showed 15 organisms per c.cm., and afte a further two days, during which time the general condition of th patient deteriorated, it was decided to discontinue sulphanilamide an begin penicillin therapy. Except for a short initial period when a intravenous drip was used, the penicillin was given by 3-hourly intramuscular injections of 15,000 units. Treatment was continued fo 10 days, and the total penicillin given was 1,157,000 units.

Osler's nodes appeared on the fingers on the same day a penicillin treatment began, and on the second day of treatment th patient had sudden pain and numbness in the left foot and leg; o examination the foot was deathly pale, and pulsation could no be felt in the left popliteal and left dorsalis pedis arteries. Th temperature, except for an occasional fall to normal, remaine about 100° F. until three days after penicillin treatment was stoppe when it remained about 99° F., probably owing to gangrene, whic had developed in the left foot. Blood cultures performed on th second, fifth, and seventh days of treatment, and on the ninth da after treatment had ceased, were sterile.

At this stage the patient was transferred to St. Thomas's Hospit for surgical treatment of the gangrenous foot. The temperatu was normal for the next three weeks, when suppuration develope in the left foot. The temperature rose to 104.4° F., the leucocy count was 15,000, and a swab from the left foot gave a growth o *Staph. aureus* and *albus* and haemolytic streptococci (not grouped Blood cultures were sterile. After a course of sulphathiazole th temperature was normal again in seven days. The patient had anoth pyrexial bout four days later, probably associated with the septic foot. On the 41st day after transfer she had a mid-thigh amputation, developed signs of bronchopneumonia, and died five days after operation.

At necropsy the heart showed mitral stenosis and hypertrophy of the left ventricle. The mitral cusps were adherent to each other and a little thickened; there were a few warty vegetations along the line of closure. The spleen was much enlarged and showed a number of septic infarcts, containing many streptococci. The material was not cultured. There were numerous small old infarcts in the kidneys. The left femoral artery contained old thrombus at its proximal end. It may be concluded that this patient had an acute bacterial endocarditis which was apparently cured by penicillin therapy, and that she died of bronchopneumonia following a major operation.

Case IV

A primipara, aged 31, with an old history of mitral stenosis. She developed puerperal sepsis after full-term delivery and was admitted to the unit on the sixth day of illness. Her general condition was fairly good; temperature 103° F., pulse rate 136, and B.P. 110/60. The heart was not enlarged; there was an apical systolic murmur, but no presystolic murmur and no thrill. There were no local signs of genital tract sepsis, and the lungs and C.N.S. were normal. A blood count showed R.B.C. 3,650,000, Hb 38%, and W.B.C. 16,000. Cultures from the cervix and blood were sterile. The urine contained no pus or red cells, but culture revealed Group A haemolytic streptococcus. Sulphanilamide treatment was given for six days (total drug, 28 g.). On the fourth day of treatment the temperature fell to 97° F. in the morning, but rose to 100° in the evening, after which a remittent fever developed, sometimes reaching 103°. A second blood culture 10 days after admission showed Group A streptococcus, and a second course of chemotherapy with sulphapyridine was started. While the drug was being given the blood cultures remained positive, and quantitative blood culture at the end of the course of sulphapyridine showed 129 organisms per c.cm. The patient's general condition was then worse; there was an apical systolic murmur as before, but no diastolic murmurs, the pulse rate was 144, and petechiae were present on the neck and tender red areas on the fingers. The spleen was not enlarged, but haematuria appeared for the first time; Hb was 55% and the W.B.C. 30,000. Penicillin treatment was begun 13 days after obtaining the first positive blood culture. The drug was given at first by 3-hourly intramuscular injections of 15,000 units, but later the interval between doses was increased. Treatment was continued for 14 days, and the total dose of penicillin was 960,000 units.

Within 24 hours of beginning penicillin treatment there was considerable clinical improvement; repeated blood cultures proved sterile, the temperature fell from 104.6° F. to 100° and remained around this level until treatment ceased, when it fell to normal. The pulse rate fell more slowly, and four days after treatment was begun a diastolic murmur was heard at the aortic area and along the left sternal border. Progress was maintained, and when the patient left hospital three months later the sedimentation rate was normal, Hb was 88%, there was a slightly diminished cardiac reserve, systolic and diastolic murmurs were heard at the aortic and mitral areas, the B.P. was 130/60, and she had a collapsing pulse.

After she left hospital the patient was seen by Dr. Jenner Hoskin, who reported: " She now has aortic regurgitation and double mitral disease, which in my opinion is rheumatic in origin. In my opinion the heart has suffered materially from the recent illness, which has definitely aggravated the valvular damage."

Case V

A multipara, aged 29, with no illnesses of note in the past history. She was admitted to the unit two days after she had aborted. She was only slightly ill; temperature 99° F., heart normal except for tachycardia of 116, B.P. 130/80. Cervical swab culture showed *Staph. aureus*; blood culture was sterile. Within 24 hours of admission to hospital she had severe haemorrhage, and manual evacuation of the uterus was performed. During the next seven days she received 47 g. of sulphanilamide. Eleven days after operation the temperature rose to 104° and blood culture showed *Staph. aureus*. A second course of sulphonamides was begun, being continued for eight days (30 g. of sulphathiazole by intravenous drip and 42 g. orally; 28 g. of sulphapyridine orally); the maximum drug concentration attained in the blood was 3.7 mg. of sulphapyridine per 100 c.cm. The general condition deteriorated; four blood cultures taken during chemotherapy were positive, and quantitative cultures on the sixth, seventh, and eighth days of treatment showed respectively 75, 120, and 703 organisms per c.cm. Penicillin treatment was then begun. The clinical picture was that of severe septicaemia without evidence of endocarditis.

Penicillin was given by 3-hourly intramuscular injections of 15,000 units for five days, then 3-hourly intramuscular injections of 10,000 units for two days; total penicillin, 790,000 units. The general condition improved considerably with the treatment, and blood cultures were sterile; but three days after treatment was stopped a rigor occurred, quantitative blood culture showed 167 organisms per c.cm., heart failure with pulmonary oedema developed, and a loud harsh pulmonary systolic murmur was heard. A second course of penicillin was given; the total dose was 879,000 units, administered during nine days by intermittent intramuscular injection. The patient's general condition again improved considerably; blood cultures were sterile on four occasions, the cardiac failure became progressively less, but six different specimens of urine contained numerous red cells. Three days after the second course of penicillin had ended acute heart failure again developed, but it responded to oxygen and diuretics; there was no pyrexia during this attack, but the pulse rate remained about 120. Six days later the temperature rose to 103° and quantitative blood culture showed 186 organisms per c.cm. No extracardiac origin was found for the septicaemia; and endocarditis, although suspected as the most probable cause for the relapses and the haematuria, was not diagnosed definitely because of the absence of petechiae, splenomegaly, and cardiac murmurs other than the pulmonary systolic. A blood count showed R.B.C. 4,100,000, Hb 68%, and W.B.C. 15,000.

A third course of penicillin was given (375,000 units during eight days by intermittent intramuscular injections). Two days after this course was begun a soft, blowing diastolic murmur which followed immediately on the second sound was heard at the aortic area and along the left sternal border. The urine contained numerous red cells, and when cultured showed some *Staph. aureus*. Blood cultures during this third course of penicillin and all subsequent blood culture were sterile. The patient continued to improve, but her discharge from hospital was delayed by chronic cystitis. She left hospital fit and well five months after her third course of penicillin had finished. Her cardiac reserve was then normal, but the aortic diastolic murmur was still well marked.

The patient was seen at the hospital 12 months later; she has been fit and well meanwhile, and has become pregnant again. She still has a diastolic murmur at the cardiac base and along the left sternal border, but it is less loud than it was before. Her B.P. is 140/70, radiographs of the heart show no abnormality, and her Wassermann reaction is negative.

Case VI

This patient, a multipara aged 31, was admitted with post-abortum puerperal sepsis and *Staph. aureus* septicaemia. She had received 31 g. of sulphonamides (13 g. of sulphamezathine and 18 g. of sulphapyridine) before admission to the unit on the seventh day of disease. She was extremely ill; temperature 100.6°, pulse 128; she was cyanosed and dyspnoeic, and had some basal pulmonary rales. Auscultation revealed an apical rumbling diastolic and an apical systolic murmur. There were numerous petechiae, especially on the neck and arms, and the spleen was slightly enlarged. *Staph. aureus* was cultured from the cervix and blood; quantitative blood culture showed 3,800 organisms per c.cm. (a repeat culture 24 hours later showed 4,820 organisms per c.cm.). The urine contained numerous red cells and some pus cells, and culture revealed *Staph. aureus*. The Hb was 58% and W.B.C. 33,000.

Penicillin treatment was started on the ninth day of disease (second day after admission) and continued for 12 days; during the first three days 120,000 units were given daily by 3-hourly I.M. injections of 15,000 units; but as the drug was slowly excreted because of chronic nephritis (urea clearance test, 16% of normal) the intervals between doses were gradually lengthened, until finally 15,000 units were given once daily, because excretion of a dose of 15,000 units was not completed until 36 hours afterwards. Total penicillin, 646,000 units. Within 24 hours of starting treatment the patient's condition improved. The temperature fell from 103° F. to normal, and it remained normal for six days, but afterwards became intermittent, sometimes reaching 100°. Blood cultures taken during penicillin treatment were sterile, but the clinical improvement was not maintained. She developed uraemia on the fifth day of treatment and became progressively worse. Death from uraemia occurred on the 21st day of disease.

The report on the necropsy was as follows: "Tricuspid valve thickened. Mitral stenosis and recent small vegetations on the valve. Cloudy swelling of the liver. The spleen contained several large infarcts and some smaller ones, most of them septic (cultures from the infarcts gave growths of *B. proteus*; Gram-positive cocci were seen in the smears, but it was not possible to determine if they were *Staph. aureus* or not). Kidneys: chronic nephritis and small infarcts in the enlarged left kidney. The uterus was slightly enlarged and without apparent sepsis. The brain had a large subdural haemorrhage; no embolism, and the arteries were normal"

Laboratory Tests

The infecting organisms in all these cases were sensitive to penicillin by *in vitro* tests. Blood and urinary levels of penicillin were determined by the methods of Fleming (1944). Penicillinase was added to blood cultures in fluid media. Quantitative blood cultures were made repeatedly in all cases by adding 1 c.cm. of blood to a tube containing 10–12 c.cm. of melted agar and pouring into a Petri dish at the bedside. We consider quantitative blood culture to be very valuable as a prognostic aid in both staphylococcal and streptococcal septicaemia, and records of cure of "septicaemia" without this check should be accepted with caution (see McLellan and Goldbloom, 1942). The presence or absence of inhibitory penicillin in the quantitative blood-culture plate was determined by streaking a culture of *Staph. aureus* on one corner of the plate before incubation.

Diagnosis of Acute Bacterial Endocarditis

Thayer (1931) wrote that in acute streptococcal and staphylococcal endocarditis the short duration of the illness and the intense septicaemia so dominate the picture that the clinical signs of petechiae, emboli, etc., associated with *Str. viridans* endocarditis uncommonly occur and the endocarditis is often indeterminable clinically. In his series petechiae and emboli occurred in only 25% of acute haemolytic streptococcal infections, and were unusual in *Staph. aureus* cases (13.8%) unless the disease was subacute, when emboli and nephritis were commonly seen after some weeks. In staphylococcal infections the spleen was generally not palpable (felt in only 12.5% of cases); suppurative arthritis occurred in 6% of cases, clubbed fingers were not observed, and red corpuscles were found in the urine only four times among 32 cases. Pericarditis was uncommon (11% of cases) in acute streptococcal endocarditis; it occurred in 13.3% of staphylococcal infections, in which it was always purulent. It was particularly noted that streptococci, both haemolytic and *viridans*, attacked the sites of congenital malformations or previously damaged valves; in his series there was evidence of pre-existing valve damage in 58% of acute streptococcal and in 71% of *Str. viridans* infections. *Staph. aureus* showed no predilection for diseased valves, and although it most commonly attacked the left side of the heart the tricuspid valve was often affected.

Until grouping of haemolytic streptococci was possible endocarditis caused by Lancefield B, C, and G organisms was not distinguishable from that caused by Group A strains, but recent reports on endocarditis caused by these organisms confirm our experience in the puerperal sepsis unit that petechiae and Osler's nodes occur infrequently in Group B and G endocarditis and that obstruction of large arteries, especially of the lower limbs, is commonly found in Group B infections. Thus, this phenomenon occurred in all three Group B cases in the present series, while of the nine Group B cases found in the literature one patient developed complete gangrene of one foot and partial gangrene of the other, one developed hemiplegia, and one developed obstruction of an iliac artery. The only Group C endocarditis (confirmed at necropsy) found in the literature developed obstruction of both iliac arteries due to an aortic embolism. The frequency of embolism in the large vessels in Group B endocarditis may be associated with the character of the vegetations. Fry, and also Ramsay and Gillespie, noted that in this condition the endocardial vegetations were large and friable, owing perhaps to the fact that Group B streptococci do not produce fibrinolysin as Group A strains do, so that the thrombus deposited on the damaged valve is not dissolved away. Massive vegetations have also been noted in Group C and G endocarditis, and occur, of course, in staphylococcal and pneumococcal endocarditis. However, in the latter infections the course of the disease is usually so acute that embolic signs may not have time to develop.

In the light of the recorded findings it may be profitable to recapitulate the criteria on which a diagnosis of acute bacterial endocarditis was made in our series of six cases. In the first three patients the repeated isolation of Group B streptococcus from the blood stream, associated with clinical evidence of a generalized infection and, with one exception, the absence of an extracardiac focus, would be strong presumptive evidence of endocarditis even before signs of valvular damage were apparent. Although a diagnosis of endocarditis was made in only one of the three cases before penicillin treatment was begun, all three developed unequivocal signs of endocardial involvement with embolic phenomena; in one the diagnosis was confirmed at necropsy. In only one of the three patients was there definite evidence of antecedent valvular damage (following acute rheumatic fever), so that Group B streptococci may attack healthy heart valves—a finding which accords with the experience of other workers. The occurrence of signs of obstruction in the large leg vessels in all three cases (followed by gangrene of the foot in one case) was probably due to arterial embolism from the friable endocardial vegetations. There was no evidence of cardiac failure or auricular fibrillation, which also predispose to arterial block.

Of the two patients with staphylococcal septicaemia, signs of endocarditis were present in one of them on admission. Although the diagnosis was confirmed at necropsy, the small size of the vegetations and the repeatedly negative blood cultures during penicillin therapy are evidence that the staphylococcal infection had been controlled. Treatment, however, had been begun too late (blood culture showed nearly 5,000 organisms per c.cm.); irremediable damage had been done, and the patient died in uraemia. The other patient with staphylococcal endocarditis had two septicaemic relapses, and evidence of endocardial damage in the form of an aortic diastolic murmur was noted for the first time during the second relapse, although haematuria, anaemia, and persistent tachycardia were present earlier. The aortic diastolic murmur, the haematuria, and negative evidence of antecedent syphilitic or rheumatic infection were accepted as proof of the development of bacterial endocarditis. Although the valvular lesion is still present, the patient is fit and well 10 months after she was discharged from hospital.

The patient with Group A streptococcal septicaemia developed signs of fresh endocardial damage during the course of her illness. She was admitted with a history of mitral stenosis and had an apical systolic but no diastolic or aortic murmur. Blood cultures were persistently positive despite intensive sulphonamide therapy, and tachycardia, anaemia, and progressive wasting were present. About the time penicillin therapy was begun Osler's nodes and haematuria occurred, and four days later an aortic diastolic murmur appeared. When discharged from hospital, and again when seen by a cardiologist about one month later, she had aortic regurgitation in addition to mitral stenosis.

The beneficial response which these patients with acute bacterial endocarditis have shown to moderate dosage of penicillin is interesting in view of the failure of similar dosage in subacute bacterial endocarditis. Part of the explanation may lie in a greater sensitivity of the infecting organism to penicillin; or perhaps the more bulky and friable vegetations may allow the penicillin to permeate the clot more easily. Although three of the patients are now well and one improved 6 to 12 months after penicillin therapy was stopped, it is impossible to say what the long-term prognosis may be. With gross valvular damage, a heavy strain is put upon their cardiac reserve and they are obviously at the mercy of any infective condition—e.g., dental sepsis—that may lead to bacteriaemia and a fresh endocardial infection.

Summary

Six cases of acute bacterial endocarditis—three due to haemolytic streptococcus Group B, two to *Staph. aureus*, and one to haemolytic streptococcus Group A—were treated with moderate doses of penicillin. Four of the patients are alive 6 to 12 months after penicillin therapy was stopped; three are well and one has improved.*

Attention is directed to the frequency of infection of healthy heart valves by Group B streptococcus, which not uncommonly causes mild genital-tract sepsis, particularly after abortion.

The criteria for the diagnosis of acute bacterial endocarditis which may occur during the course of a generalized infection are discussed.

* ADDENDUM

Since this paper was completed, patient No. II of the series has died, six months after penicillin treatment had ceased. During this period the temperature was normal, blood cultures were sterile on four occasions, and the sedimentation rate was normal. She had severe mitral disease. Chronic congestive failure, which responded to mercurial diuretics for a time, developed. Death was due to pulmonary oedema following acute left heart failure.

At the necropsy dilatation and hypertrophy of both auricles and right ventricle and dilatation of the left ventricle were found. The tricuspid orifice was enlarged and the cusps slightly thickened. The mitral orifice was rather small, the valves thickened and contracted, and there were two large perforations of the cusps. A small vegetation on the mitral valve gave a growth of *B. coli* and enterococcus on culture. The kidneys were rather large and congested, and one kidney had scars from two infarcts. It may be concluded that this patient had an acute bacterial endocarditis which was apparently cured by penicillin therapy, and that she died from acute heart failure.

We wish to thank Mr. James-Wyatt, consultant to the puerperal sepsis unit, for his interest and help; Sir Bernard Spilsbury for the post-mortem reports on Cases II and VI; Mr. B. C. Maybury and Prof. W. G. Barnard for access to clinical and necropsy reports on Case III; Sisters Corcoran and Walshe and the nursing staff of the puerperal sepsis unit for their active co-operation in the nursing of the patients; Mr. E. W. Gregory for technical assistance; and the M.R.C. Penicillin Clinical Trials Committee for supplies of penicillin.

STAPHYLOCOCCUS PYOGENES SEPTICAEMIA TREATED WITH PENICILLIN

REPORT OF TWO CASES

BY

LEONARD HOWELLS, M.D., B.Sc., M.R.C.P.
Lieut.-Col., R.A.M.C.; Officer in Charge, Medical Division of a General Hospital

R. R. HUGHES, M.D., M.R.C.P.
Major, R.A.M.C.; Medical Specialist

AND

R. RANKIN, M.B., B.Sc., Ch.B.
Capt., R.A.M.C.; Graded Pathologist

The following is an account of two cases of *Staphylococcus pyogenes* septicaemia treated with penicillin.

Case I

The patient was a marine aged 22. On Sept. 28, 1944, he developed headache, sweating, slight cough, and pain in the back; he remained on duty all night and was sent to the sick-bay the next day. On the 30th he was admitted to hospital still complaining of the above symptoms. On examination he was rather apathetic, temperature 101.6°, pulse rate 100, and respiratory rate 22 a minute; his throat was slightly injected, but no other abnormality was found.

By Oct. 1 his condition had deteriorated; his temperature was swinging to 102° F., and the pulse and respiratory rates were rising. He was confused, restless, and irritable, his heart apex beat was in the mid-clavicular line in the fifth left intercostal space, there was some neck rigidity, and Kernig's sign was slightly positive. In view of these findings a clinical diagnosis of meningococcal meningitis was made. Lumbar puncture was done under pentothal anaesthesia; the cerebrospinal fluid pressure was 200 mm., and the fluid was slightly murky in appearance; on laboratory examination it was found to contain 40 red blood cells and 9 white blood cells per c.mm. and 40 mg. of protein (no excess of globulin), 70 mg. of glucose, and 700 mg. of chlorides per 100 c.cm. The urine was loaded with albumin (0.75 g. Esbach), and on microscopical examination scanty epithelial cells, leucocytes, and granular casts were found. Blood examination showed a haemoglobin of 89%, red blood cells 4,750,000 per c.mm., and white blood cells 14,000 per c.mm., with 85% polymorphonuclears.

On Oct. 2 the patient was still confused and irritable, with a temperature swinging to 102° F. and raised pulse and respiratory rates. On examination the neck rigidity and Kernig's sign were more pronounced, the fundi were normal, all tendon reflexes were absent, and plantar responses showed voluntary withdrawal of both feet. The heart was enlarged, with the apex beat 4½ in. from the midline in the fifth left intercostal space, a systolic murmur was heard at the apex and base of the heart, and the blood pressure was 140/60. The white cell count had now risen to 23,600 per c.mm., with 84% polymorphs, the blood urea was 55 mg. per 100 c.cm., the urine was still loaded with albumin, and leucocytes and granular casts were still present.

During the day the patient's pulse rate had been rising steadily, and at 22.00 hours had reached 142 a minute. At this time he suddenly developed a left hemiparesis involving the limbs and face, and on examination his heart was found to be more dilated and the systolic murmur still present. In view of these developments it was now felt that a clinical diagnosis of infective endocarditis could be made; although this had not yet been confirmed by blood-culture the dangerously ill condition of the patient made immediate specific treatment essential. Penicillin therapy was therefore started; he was given 100,000 units at 23.30 hours, followed by 40,000 units intramuscularly 3-hourly day and night.

By 09.00 hours on Oct. 3 he had been given 220,000 units of penicillin. His general condition had improved somewhat and his pulse rate had fallen to 108 a minute, but he was still in a state of low muttering delirium, his neck rigidity was more marked, and his hemiplegia was unchanged. The urine was loaded with albumin, the blood urea was 80 mg. per 100 c.cm., and the cerebrospinal fluid now contained 376 red blood cells per c.mm. Blood and cerebrospinal fluid cultures were made on this date and later; both were reported to contain *Staph. pyogenes*. The bacteriological report was as follows: "A smooth-growing well-pigmented strain of *Staph. pyogenes* was isolated after 36 hours. The organism was coagulase-positive, moderately haemolytic, and showed a sensitivity to sodium penicillin equalling that of the standard 'Oxford' strain." When re-examined at 19.00 hours his general condition was unchanged. He was still delirious, the neck rigidity and hemiparesis were still pronounced although he could now use his left arm a little, his heart apex beat was 1 in. outside the left mid-clavicular line in the fifth intercostal space, and a soft short apical diastolic murmur could be heard. The spleen was not palpable.

On Oct. 4 there was an improvement in the patient's general condition, his temperature had settled to the region of 99° F., and his pulse rate was steadily falling. He was, however, still delirious and the neck rigidity and hemiparesis were severe; the heart apex beat was well outside the left mid-clavicular line, and the soft apical diastolic murmur could still be heard. The blood urea was 60 mg. per 100 c.cm. On the 5th the patient's temperature was normal and his pulse and respiratory rates were falling rapidly. He was still very ill, but his condition had improved in the past 24 hours and he was having short lucid intervals. A crop of purpuric spots had appeared on the toes of both feet. The cerebrospinal fluid pressure was 250 mm.; the fluid contained 167 red blood cells per c.mm., and on culture was sterile. By 20.30 hours he had been given 1,020,000 units of penicillin; his condition was rapidly improving; he was fully conscious, with only occasional short periods of confusion, and was able to use his left hand to hold a feeding-cup.

By Oct. 6 the patient's condition had very much improved and he had been afebrile for the past 24 hours. He was still having occasional slight delirium and his neck rigidity was more pronounced; his hemiparesis was improving and he was now moving his left arm and leg a good deal. There was a left extensor plantar response. The heart apex beat was still well outside the mid-clavicular line in the fifth left intercostal space; there was a soft localized aortic systolic and a harsh apical diastolic murmur. The liver and spleen were not palpable. The blood urea was 55 mg. per 100 c.cm., the urine still contained albumin, and there were some leucocytes and an occasional granular cast in the deposit.

On Oct. 7 he was using his left arm and leg a good deal although weakness persisted; his condition was otherwise unchanged; and he was delirious at times. The next day an aortic diastolic murmur was heard for the first time. The white blood count was 14,150 per c.mm. with 81% polymorphs. A course of sulphapyridine was started with an initial dose of 2 g., followed by 2 g. four hours later, then 1 g. 4-hourly by mouth.

On Oct. 9 his general condition was very good, his appetite was satisfactory, and he was sleeping well with only very few short periods of delirium. He was still having an occasional rise of temperature to 99 or 100° F. On examination the heart apex beat was in the mid-clavicular line in the fifth left intercostal space; there was no palpable thrill. Auscultation revealed a rough aortic systolic murmur which was conducted along the subclavian and carotid arteries, and also a soft short aortic diastolic murmur conducted down the left border of the sternum. The pulse was collapsing, the blood pressure 140/40, and a pistol-shot murmur was audible over the femoral arteries. The spleen was not palpable. He was now using the left arm normally, but there were a slight weakness of the left lower face, a spastic left leg, and a left extensor plantar response. The abdominal reflexes were present but diminished on the left side. The blood urea had now fallen to 45 mg. per 100 c.cm. Radiographs showed definite enlargement of the heart to the left, with the general configuration of an early aortic lesion. There was also some hyperaemia at the base of the right lung.

The patient's condition was still improving on Oct. 10 and his neurological signs had almost completely cleared. On this date a number of large haemorrhagic blisters appeared on the hands and feet. Red blood cells were found in the urine for the first time (specimens had been examined daily for these since admission). By the 12th he had had a total of 3,020,000 units of penicillin, and although there was an occasional rise of temperature to 99 or 100° the drug was discontinued. By Oct. 18 the patient's condition was excellent and he had been afebrile for the past 7 days. There was still some slight weakness of the left face, the to-and-fro aortic bruit was unchanged, and the heart was enlarged; the heart sounds, however, were much stronger. The blood count showed a haemoglobin of 79%; the red blood cells numbered 3,700,000 and white cells 10,600 per c.mm., with 68% polymorphs. The blood sedimentation rate was 4 mm. in 1 hour, and the urine still contained a few leucocytes, red cells, and granular casts. The sulphapyridine was now discontinued after a total dose of 50 g.

The patient was still very well on Oct. 23. He had been afebrile since the 11th; but the pulse rate was rising, and varied between 84 and 108 a minute. On examination there was slight weakness of the left lower face and of the left arm and leg, the abdominal reflexes were somewhat diminished on the left side, the left knee- and ankle-jerks were both slightly increased, and both plantar responses were flexor. The heart apex beat was 3½ in. from the midline in the fifth left intercostal space, the to-and-fro aortic murmur was still present but now very faint, and there was still a pistol-shot sound over the femoral and brachial vessels. The systolic blood pressure was 148 mm., the diastolic uncertain but probably about 48 mm. Hg.

On Nov. 11 he was feeling very well, and his appetite and sleep were good. He continued to be afebrile, but his pulse rate remained at 90 to 100 a minute. On examination there was a slight weakness of the left lower face; the left arm and leg were both normal and the plantar responses flexor. The heart apex beat was still diffuse and heaving, 4 in. from the midline in the fifth left intercostal space. On auscultation a rough systolic bruit could be heard over the whole of the praecordium, but was loudest in the aortic area and was conducted slightly along the carotid and subclavian arteries; a soft diastolic bruit was also audible over the whole praecordium, but loudest in the pulmonary area. The lungs and abdomen were normal; the spleen was not palpable. The blood sedimentation rate was 0.5 mm. in 1 hour; the Kahn test was negative and the blood count showed a haemoglobin of 85%, red cells 4,010,000, and white cells 9,300 per c.mm., with 69% polymorphs. The pulse was collapsing in type, the blood pressure 150/30, and a pistol-shot murmur was audible over both brachial and femoral vessels. On Nov. 11 he was evacuated to the United Kingdom.

Comment on Case I

This was a typical case of infective endocarditis due to *Staph. pyogenes* treated with penicillin and sulphapyridine. No primary focus was found, there being no evidence of staphylococcal infection and no history of any such condition. When the case was first seen the diagnosis was obscured by a subarachnoid haemorrhage and a hemiparesis, presumably the result of the rupture of a mycotic aneurysm; by the fifth day of the disease, however, the cardiac changes were definite enough to venture a clinical diagnosis, this being confirmed later by isolation of the organism from the blood and cerebrospinal fluid. Penicillin treatment was begun on the fifth day of the disease, and within 52 hours the temperature had fallen to normal: 3,020,000 units were given over a period of nine days. However, as he still showed occasional rises of temperature, this was followed by a course of 30 g. of sulphapyridine.

During the early stages of the illness the patient had the usual features of a septicaemia: temperature swinging to 102° F., rapid pulse and respiratory rates, a white blood cell count up to 23,000 per c.mm., and a haemoglobin which fell from 89% on the fourth day to 79% on the nineteenth day of illness. After treatment of the disease the temperature had been normal for 26 days, the white cell count was 9,300 per c.mm., the haemoglobin had risen to 85%, and the blood sedimentation rate was 0.5 mm. in 1 hour. One unsatisfactory feature was a pulse rate remaining persistently at the 90–100 level despite complete bed-rest.

The embolic phenomena were of particular interest. On the day after admission to hospital the patient was noted to have signs of slight meningeal irritation, and on lumbar puncture his cerebrospinal fluid was found to contain 40 red blood cells per c.mm. The meningeal signs gradually increased in severity, and 24 hours later he suddenly developed intense neck rigidity and a left hemiparesis, and the cerebrospinal fluid contained 376 red cells per c.mm. The neck rigidity gradually subsided during the next week. The hemiparesis was more persistent, but it improved steadily, and on discharge all that remained was slight weakness of the left lower face and minimal changes in the reflexes on the left side. It seems likely that the patient had an infected cerebral embolus which produced a mycotic aneurysm very early in the course of the disease, leaking slightly at first, and later more severely to produce a focal cerebral lesion. Other embolic manifestations were a crop of purpuric spots and, later, numerous large haemorrhagic vesicles on the toes and feet. Osler's nodes were not seen; there were no retinal emboli and no splenic enlargement at any time.

The renal changes provided some interesting and confusing features. At the time of the intracranial haemorrhage (the fourth day of the disease) there was heavy albuminuria, with granular casts in the urine and a blood urea estimated two days later at 80 mg. per 100 c.cm.; such changes are not uncommon with acute intracranial conditions like haemorrhage and meningitis, and are apparently not associated with renal damage. Together with the mental disturbance they raised the possibility of uraemia at that stage of the illness. The urine was examined for red blood cells each day, but these were not found until the 13th day of the disease; by this time the blood urea had fallen to 45 mg. per 100 c.cm., and there remained only a trace of albumin together with granular casts in the urine. These later changes were probably due to an embolic focal nephritis, and persisted for some time.

When questioned about previous heart trouble, after the acute phase of the illness was past, the patient admitted to an attack of "rheumatism" in childhood. This seems to have left no gross heart lesion, as he was able to exercise without undue discomfort and no heart lesion was discovered at several medical examinations during his naval service. On admission to hospital his heart was clinically normal; during the acute stages of the disease it rapidly enlarged, various changing murmurs were produced, and on the fifth day of the illness the blood pressure was 140/60. It was not until the 11th day that an aortic diastolic murmur was heard, and the following day his case had the classical features of an aortic regurgitation. On consideration of these findings it seems possible that there may have been some slight rheumatic damage to the aortic valve which determined the localization of the septicaemia in this situation, and that this damage was much increased by the present illness. As the septicaemic condition subsided the heart diminished in size, and we are under the impression that the murmurs became less intense, but at the time of discharge from hospital there could be no doubt that he had a severe aortic leak.

While, in view of the short period of observation, it is realized that the result in this case cannot be regarded as an undoubted cure, we feel that it is most encouraging and that penicillin is worthy of trial in other cases of this condition.

Case II

The patient, a sapper aged 24, was admitted to hospital on Aug. 27, 1944. His illness had begun on Aug. 21 with a sore throat, fever, and general malaise. On admission he looked ill; his temperature was 103° F., pulse rate 100, and respiratory rate 25 a minute. The tonsils were considerably enlarged, oedematous, and covered by a yellowish follicular exudate. There were no abnormal signs in the heart, lungs, abdomen, or central nervous system. Examination of a throat swab was reported upon as follows: "Direct film showed Vincent's organisms and a few Gram-positive cocci, and on culture non-haemolytic streptococci and a scanty growth of staphylococci were obtained; examination for K.L.B. was negative." He was given sulphanilamide, 2 g. initial dose, followed by 1 g. every four hours. On Aug. 28 he had two rigors, the temperature reaching 103.8° F.

On Aug. 29 there was a slight deterioration in his general condition, with no change in the appearance of the throat but a decrease in the fever during the day. A pleural friction rub was heard in the right axillary region. The urine contained a trace of albumin. Examination of a blood film for malaria parasites was negative. The total white cell count was 7,200 per c.mm., with 50% polymorphonuclears, 8% small lymphocytes, 30% large lymphocytes, and 12% monocytes. He had now received 12 g. of sulphanilamide with no apparent improvement, so it was decided to substitute sulphathiazole, 1 g. every four hours, instead.

During Aug. 30 and 31 the fever varied from 97 to 103° F.; the pulse rate rose to 128 a minute, and he was now seriously ill with no change in the condition of the throat. On Sept. 1 the spleen was palpable clinically for the first time, the pleural friction rub persisted, and he began to expectorate blood-stained sputum. The tonsils were still greatly enlarged and covered by a yellowish exudate. Sputum examination for tubercle bacilli was negative.

Blood culture on Sept. 2 gave a good growth of *Staph. pyogenes* (confirmed two days later, when another good growth was obtained). The organism had the following characteristics: a smooth moderately pigmented strain of *Staph. pyogenes*, non-haemolytic, coagulase-positive; penicillin sensitivity equal to that of the standard "Oxford" strain. It was now clear that the patient had a general septicaemia, and in spite of having received 12 g. of sulphanilamide and 25 g. of sulphathiazole he was getting steadily worse. Sulphathiazole treatment was stopped, and at 22.00 hours penicillin was given instead, in doses of 16,666 units, by intramuscular injection every three hours. The temperature at 22.00 hours was 102° F., and the pulse rate 110 a minute. No pathogens were obtained from culture of a throat swab. The total white cell count was still relatively low considering the nature of the infection—namely, 6,800 per c.mm., with 50% polymorphs, 27% small lymphocytes, 19% large lymphocytes, and 4% monocytes. On Sept. 3 and 4 a slight lowering of the temperature and some improvement in his general condition were apparent. On the 5th the temperature dropped to normal and was accompanied by a striking improvement in the patient's general condition and in the local appearance of the throat. The spleen was no longer palpable and the pleural friction rub could not be heard.

Subsequent Progress.—There was a rise of temperature to 100° F. on Sept. 6 and 7 and to 99° F. on Sept. 9 and 10, but subsequently the temperature and pulse rate remained at normal levels. Penicillin was discontinued on Sept. 11, as the patient had now received 1,133,288 units. By this time all clinical evidence of septicaemia had gone and the appearance of the throat was normal. He continued to make an uneventful recovery, with no residual signs of disease in any system, and on Sept. 20 was evacuated to the United Kingdom for a period of convalescence.

Comment on Case II

This was a case of *Staph. pyogenes* septicaemia associated with acute tonsillitis. The patient's resistance against the infection was poor, as was evidenced by a serious deterioration in his clinical condition and by the unsatisfactory white blood cell response. Treatment with 12 g. of sulphanilamide followed by 25 g. of sulphathiazole failed to produce any improvement in the local tonsillar infection or in the general condition of the patient. Penicillin was administered at a critical stage of the illness, and within 56 hours was followed by a dramatic improvement and, a few days later, by a complete and uncomplicated recovery.

Summary

The above two cases present encouraging features in the treatment of *Staph. pyogenes* septicaemia with penicillin. In the first case the favourable result was probably assisted by sulphapyridine therapy, but in the second case sulphanilamide and sulphathiazole each failed to produce any improvement in the condition. It is felt that these results may encourage others to employ and observe the effect of penicillin therapy in similar cases.

We wish to thank Col. F. G. Flood, *M.C.*, officer commanding the military hospital, for permission to publish this report.

The 150th annual report by the Managers of Glasgow Royal Infirmary, for the year 1944, shows that a very large volume of work was done for the sick and injured from all parts of Britain, including a great many Service cases treated in the wards. For a long time wards have been set aside for the treatment of burns, and more of these injuries have been dealt with at the Glasgow Royal Infirmary than at any other hospital in the British Isles. In view of the need for further research on various aspects of the treatment of burns, the Medical Research Council, in agreement with the managers of the Infirmary, decided to appoint a junior surgeon to give whole-time assistance to Mr. A. M. Clark, who has been in charge of the burns wards for several years, and to establish a laboratory team to survey the problem along with other members of the staff. During last year 318 patients suffering from burns and scalds were admitted. The outstanding features were the greatly reduced death rate—5.6%—and the elimination to a very large extent of streptococcal infection, the main source of trouble in burns. All out-patients with burn injuries are now treated in the Unit; they number about a thousand a year. During 1944 the Infirmary received a very considerable supply of penicillin for the treatment of military and civilian cases. Large supplies were distributed to other hospitals in Glasgow, Lanarkshire, Stirlingshire, and Renfrewshire, and the Infirmary is not only a distributive centre but an advisory centre for the use of penicillin.

LOCAL PENICILLIN THERAPY IN OPHTHALMIA NEONATORUM*

BY

ARNOLD SORSBY, M.D., F.R.C.S.

(White Oak (L.C.C.) Hospital, Swanley)

In an earlier communication (Sorsby and Hoffa, 1945) an account was given of the use of penicillin for local therapy in 47 cases of ophthalmia neonatorum. It was shown that consistent results could be obtained when drops in a concentration of not less than 2,500 units per c.cm. were used; of 22 cases so treated 21 recovered, against only 3 out of 8, 4 out of 7. and 6 out of 10 treated with penicillin in concentrations of 500, 1,000, and 1,500 units respectively. The gratifying results obtained with penicillin in adequate concentration had been achieved by instilling one drop of the solution at half-hourly intervals for 3 hours, then hourly for 24 hours, and 2-hourly subsequently. None of these 21 successfully treated cases took longer than 100 hours to show a clinical cure, and in 6 cases clinical cure was obtained within 3 to 24 hours. It was indicated that all the common causal organisms of ophthalmia neonatorum, including the virus of inclusion blennorrhoea, appeared to respond to penicillin, though perhaps to varying degrees, diphtheroid bacilli probably being the most resistant.

A Further Series of 38 Cases

Like the last 22 cases in the previous series these 38 new cases have all been treated with penicillin in a concentration of 2,500 units per c.cm., but the frequency of instillation has been different: at longer intervals in 13 and at shorter intervals in 25 cases.

(*a*) *Thirteen cases treated with drops of penicillin at intervals of 1 hour for 6 hours, then 2-hourly for 24 hours, and subsequently at 3-hourly intervals.*—All these responded well, but one case relapsed after 24 hours and another after 5 days (both of these being finally cleared by a course of sulphamezathine for 5 days and 2 days respectively). The clinical details on these 13 cases are summarized in Tables I and II.

TABLE I.—*Time taken for Clinical Cure: in Relation to Severity and Distribution of the Affection*

	No. of Cases	Clinical Cure in
Mild:		
Unilateral	3	4, 48, and 56 hours respectively
Bilateral	0	
Moderate:		
Unilateral	2	30* and 38 hours respectively
Bilateral	3	58, 60,† and 60 hours respectively
Severe:		
Unilateral	1	20 hours
Bilateral	4	4, 18, 26, and 34 hours respectively

* Mild relapse after 24 hours. † Relapse after 5 days.

TABLE II.—*Time taken for Clinical Cure: in Relation to Causal Organism and Severity of the Affection*

	No. of Cases	Clinical Cure in
Gonococcus:		
Mild	1	4 hours
Moderate	0	
Severe	3	20, 26, and 34 hours respectively
Gram-positive cocci		
Severe	1	18 hours
Staph. aureus:		
Severe	1	4 ,,
Diphtheroids:		
Mild	1	56 ,,
Inclusion bodies present (with Gram-positive cocci and Gram-positive bacilli respectively):		
Moderate	2	30* and 38 hours respectively
No organisms or inclusion bodies present:		
Mild	1	48 hours
Moderate	3	58, 60,† and 60 hours respectively

* Mild relapse after 24 hours. Inclusion bodies were also present in scrapings from the mother's cervix.

† Relapse after 5 days. The culture had shown the presence of *Ps. pyocyanea*, probably a contaminant.

These results do not appear to be substantially different from those obtained in the 22 cases treated at more frequent intervals.

---

* A report to the Penicillin Clinical Trials Committee of the Medical Research Council.

(*b*) *Twenty-five cases treated with drops of penicillin initially at intervals of 5 minutes, then half-hourly, and subsequently hourly, followed by 2-hourly intervals.*—This unusual procedure requires some explanation. In the previous communication it was reported that when penicillin is used at half-hourly intervals irrigation was generally required before the first 12 applications of drops—i.e., for the first 6 hours of treatment. As drops are washed out of the conjunctival sac within a matter of minutes it was thought desirable to instil penicillin at 5-minute intervals. It was then found that no further irrigation was needed beyond the first one carried out before instilling the penicillin, for all tendency to the formation of pus was rapidly suppressed. When all discharge had ceased penicillin was continued at half-hourly intervals till the eye was dry; thereafter it was instilled hourly for 12 hours and 2-hourly for a further 24 hours. In this series 2 cases showed a distinctly poor response. One was a case of moderate bilateral gonococcal ophthalmia in a premature baby. Sulphamezathine treatment cleared the eyes within 3 days, only to relapse after 13 days and to be cleared finally by a second course of this sulphonamide. The second case was also of moderate severity; diphtheroids were present in the smear, but the culture was negative. This case responded well to sulphamezathine within 4 days.

The clinical details of this group of cases are shown in the following summary tables (III and IV).

Table III.—*Time taken for Clinical Cure: in Relation to Severity and Distribution of the Affection*

	No. of Cases	Clinical Cure in
Mild:		
Unilateral	3	3, 6, and 21 hours respectively
Bilateral	3	25 minutes, 1⅓, and 16 hours respectively
Moderate:		
Unilateral	1	22 hours*
Bilateral	12	3,† 3⅙, 3¼, 5¾, 6⅓, 7, 11½,‡ 13½, 33,§ and 38 hours respectively, with 2 further cases showing no response
Severe:		
Unilateral	0	
Bilateral	6	4, 10, 10, 10½, 16, and 16½‖ hours respectively

Table IV.—*Time taken for Clinical Cure: in Relation to Causal Organism and Severity of the Affection*

	No. of Cases	Clinical Cure in
Gonococcus:		
Mild	1	1½ hours
Moderate	1	No response
Severe	3	4, 10, and 10½ hours respectively
Staph. aureus:		
Mild	1	6 hours
Moderate	5	5¾, 6⅓, 7, 11½,‡¶ and 22* hours respectively
Severe	2	10 and 16½‖ hours respectively
Diphtheroids:		
Moderate	3	3† and 3⅙ hours, and no response respectively
Haemolytic streptococcus:		
Mild	1	25 minutes
Gram-neg. diplococcus:		
Moderate	1	33 hours§
Friedländer's bacillus:		
Mild	1	16 ,,
Morax-Axenfeld bacillus:		
Severe	1	16 ,,
No organisms or inclusion bodies:		
Moderate	1	13½ ,,
Inclusion bodies present without organisms:		
Mild	1	21 ,,
Moderate	1	38 ,,
Inclusion bodies present with organisms (diphtheroids and Gram-positive cocci respectively):		
Mild	1	3 ,,
Moderate	1	3¼ ,,

Footnotes to Tables III and IV

* Relapsed after 24 hours. A second course of penicillin brought about a clinical cure in 8 hours, only to relapse again. Finally cleared by sulphamezathine in 3 days.

† Mild relapse; cleared by a further course in 4 hours.

‡ Relapse 5 days later. Sulphamezathine for 68 hours; baby removed against advice with eyes not quite clear.

§ Mild relapse after 6 days. Cleared by further course of penicillin in 41 hours.

‖ Mild relapse 4 days later. Cleared by a further course in 2½ hours.

¶ Inclusion bodies were present in scrapings from the mother's cervix.

This group of 25 cases therefore contains 2 that showed no response to intensive penicillin therapy and no fewer than 5 which showed initial clinical cure only to be followed by a relapse, which, however, was cleared in 3 out of the 5 cases by a second course of penicillin, suggesting that too early suspension of treatment rather than inefficacy of penicillin was responsible for these partial failures. In contrast to these 2 total and 5 partial failures the remaining 18 cases showed distinctly gratifying results, the time taken for clinical cure being 38 hours at the longest and 25 minutes at the best, with an average of just under 10 hours. The following summary table (V) brings out the essential features:

Table V

Time taken for Clinical Cure	Number of Cases
Up to 1 hour	1
1–4 hours	4
4–8 ,, ...	5
8–12 ,, ...	3
12–16 ,, ...	1
16–20 ,, ...	2
21 ,, ...	1
38 ,, ...	1

The 5 cases that relapsed had initially showed clinical cure in 3, 11½, 16½, 22, and 33 hours respectively; the 2 cases that had failed to respond had been treated for 40 and 72 hours respectively.

So far as the time taken for clinical cure is concerned, these 18 successful cases (out of 25) compare favourably with the 20 comparable cases (out of 22) and the 11 (out of 13) treated by the same concentration of penicillin but less intensively. The comparative figures in Table VI show this clearly:

Table VI.—*Penicillin Drops in Concentration of 2,500 Units*

Time taken for Clinical Cure	Initial Treatment		
	At 5-minute Intervals	At Half-hourly Intervals	At Hourly Intervals
	Cases	Cases	Cases
Within 12 hours	13	2	2
12–24 hours	4	4	2
25–48 ,, ...	1	7	4
49–72 ,, ...	—	3	3
Over 72 ,, ...	—	4	—
Total	18	20	11

Average time per case: 10, 44, and 33 hours in the three series respectively.

It would therefore appear that intensive penicillin therapy (at 5-minute intervals) reduced the time taken for a clinical cure to one-third or one-quarter of that required when this drug is applied at hourly or half-hourly intervals.

Rapidity of Clinical Cure in Relation to Severity of Affection

No fine distinctions as to any difference in response by heavy and less heavy infections can be drawn from the limited material so far available. There is nothing to suggest that clinically

Table VII

	Initial Treatment		
	At 5-minute Intervals (25 Cases)	At Half-hourly Intervals (22 Cases)	At Hourly Intervals (13 Cases)
Mild ..	6 cases: clinical cure in 25 minutes to 21 hours Average: 8 hours No failures No relapses	5 cases: clinical cure in 7 to 78 hours Average: 51 hours No failures No relapses	3 cases: clinical cure in 4 to 56 hours Average: 36 hours No failures No relapses
Moderate	13 cases: clinical cure in 3 to 38 hours Average (of 11 cases): 13 hours *Two failures* *Four relapses*	11 cases: clinical cure in 3 to 100 hours Average: 46 hours No failures No relapses	5 cases: clinical cure in 30 to 60 hours Average: 41 hours No failures *Two relapses*
Severe ..	6 cases: clinical cure in 4 to 16½ hours Average: 11 hours No failures *One relapse*	6 cases: clinical cure in 36 to 40 hours Average (of 5 cases): 37 hours *One failure* No relapses	5 cases: clinical cure in 4 to 34 hours Average: 16 hours No failures No relapses

severe cases respond less readily. In fact, in the present series the troublesome cases were almost confined to the group regarded as moderate; the 2 cases that gave no response to penicillin and 6 of the 7 cases that showed relapse were all initially cases of moderate severity. The summary of results given in Table VII, which includes the series of 22 comparable cases previously reported, brings out the salient features.

Efficacy in Relation to Causal Organisms

The following summary table of aetiological types (Table VIII) brings out the time taken to achieve clinical cure in the successfully treated cases and the number of failures and of relapses in each group. The table deals with the 38 cases recorded here and the 22 previously reported.

TABLE VIII

	Initial Treatment		
	At 5-minute Intervals (25 Cases)	At Half-hourly Intervals (22 Cases)	At Hourly Intervals (13 Cases)
Gonococcus	5 cases: 1½ to 10½ hours Average (of 4 cases): 7½ hours *One failure* No relapses	5 cases: 24 to 40 hours Average (of 4* cases): 35 hours No failures No relapses	4 cases: 4 to 34 hours Average: 21 hours No failures No relapses
Staph. aureus	8 cases: 5¾ to 22 hours Average: 10½ hrs. No failures *Three relapses*	5 cases: 3 to 60 hours Average: 20 hours No failures No relapses	1 case: 4 hours No failures No relapses
Staph. albus	—	4 cases: 27 to 43 hours Average: 37 hours No failures No relapses	—
Diphtheroids	3 cases: 3 and 3⅛ hours respectively (in 2 cases) *One failure* *One relapse*	4 cases: 50 to 100 hours Average (of 3 cases): 83 hours *One failure* No relapses	1 case: 56 hours No failure No relapse
Haemolytic streptococcus	1 case: 25 mins. No failure No relapse		
Gram-negative diplococci	1 case: 33 hours No failure *Relapse*		
Friedländer's bacillus	1 case: 16 hours No failure No relapse	—	—
Morax-Axenfeld bacillus	1 case: 16 hours No failure No relapse		
Gram-positive cocci	—	—	1 case: 18 hours No failure No relapse
No organisms or inclusion bodies	1 case: 13½ hours No failure No relapse	2 cases: 12 and 70 hours respectively No failures No relapses	4 cases: 48 to 60 hours Average: 57 hours No failures *One relapse*
Virus presumed from presence of inclusion bodies	4 cases: 3 to 38 hours Average: 16 hours No failures No relapses	2 cases: 78 and 100 hours respectively Average: 89 hours No failures No relapses	2 cases: 30 and 38 hours respectively No failures *One relapse*

* One case omitted, as the complication of corneal ulcer—present on admission—delayed a return to normal.

In this total of 60 cases there were therefore 1 failure in a series of 14 cases showing the gonococcus and 2 failures in a series of 8 cases showing diphtheroids; there were no failures in the 14 cases due to *Staph. aureus* and in the 4 showing *Staph. albus*, while the single cases due to *Str. haemolyticus*, Friedländer's bacillus, Morax-Axenfeld bacillus, Gram-negative diplococci, and Gram-positive cocci all responded. It would therefore seem that all the common causal organisms of ophthalmia neonatorum respond to penicillin therapy; no real significance can be attached to the 3 failures (1 gonococcus and 2 diphtheroids) in view of the satisfactory response in other (and more) cases of this type. It is also noteworthy that no failures were seen in the 7 cases in which no organism or inclusion bodies were present and in the 8 cases in which a virus appeared to be the responsible agent, judging by the presence of epithelial inclusion bodies.

At this stage it is unwarrantable to draw any conclusions as to greater clinical susceptibility of the different varieties of ophthalmia neonatorum to penicillin, but it is clear that neither the occasional failures nor relapses are explicable in terms of bacterial morphology.

Mode of Use

For the present something like a 5-stage system is in use:

1. On admission a swab is taken for smear and culture and the eye is irrigated with half-normal saline at room temperature. A drop of adrenaline 1 in 1,000 is instilled and a scraping is taken from the palpebral conjunctiva for examination for the presence of inclusion bodies. Gutt. atropin. sulph. 1% are instilled if the cornea is involved.

2. Any pus that may have accumulated is wiped away with moist pledgets of cotton-wool, and one drop of penicillin in a concentration of 2,500 units per c.cm. is instilled. The baby is now returned to its cot.

3. The instillation of penicillin is continued every 5 minutes until there is no discharge. Irrigation is not needed, as pus does not form to any extent; such thin mucoid discharge (with a yellowish tinge from the admixture of penicillin) as is present can be ignored, or, if it clings to the lid margin, wiped away with moist pledgets of cotton-wool. Generally half an hour to three hours' treatment (6 to 30 applications) is necessary before the eye is dry. This part of the treatment requires the full-time attention of the nurse.

4. When there is no longer any discharge the instillation of penicillin is continued at half-hourly intervals. At this stage the conjunctiva rapidly assumes a normal appearance. When all swelling and tendency to moistness have disappeared—and this generally involves treatment for about 6 to 12 hours—penicillin therapy is continued to consolidate the clinical cure.

5. Penicillin is now instilled hourly for 12 hours and 2-hourly for a further 24 hours.

Penicillin is well tolerated by the infant eye; occasionally a mild transitory flushing of the conjunctiva is observed. (In the present series—as in the previous one—no complications of any kind have been observed, but in a case treated subsequent to those recorded here there was an instantaneous and marked swelling of the conjunctiva and lids on the instillation of penicillin in the form of a lamella; the swelling subsided within 12 hours, the child having in the meantime been put on sulphamezathine treatment.)

Comparison with General Sulphonamide Therapy

It is likely that general sulphonamide therapy of ophthalmia neonatorum is already obsolete as a routine procedure. The results obtained by the intensive application of penicillin locally are almost as strikingly superior to those obtained by sulphonamide therapy as these in turn were over the older methods. The reduction of the duration of treatment from weeks by the older methods to days by the sulphonamides is paralleled by the reduction of treatment from several days by the sulphonamides to as many hours by penicillin. Should it prove possible to standardize penicillin therapy to a less exacting routine than is required at present, an ideal method of treatment, free from the disadvantages of systemic medication, will indeed be achieved.

Summary

Local therapy by penicillin in a concentration of 2,500 units per c.cm. proved effective in 21 out of 22 cases of ophthalmia neonatorum reported previously.

In a further series of 38 cases reported here, 2 cases failed to respond.

Twenty-five of 38 cases had been treated by intensive application of penicillin (drops instilled every 5 minutes). The results were better than those obtained by the instillation of penicillin at half-hourly intervals (as in the 22 cases reported previously) or at hourly intervals (as in 13 cases in the present series).

The 25 cases treated intensively included the 2 cases that showed no response and 5 cases that relapsed after initial clinical cure; 4 of these 5 relapses responded well to a second course of penicillin. Of the 18 cases that responded initially to treatment 13 showed clinical cure within 12 hours, and a further 4 within 12 to 24 hours.

Severity of the clinical condition does not appear to affect the duration of treatment.

Penicillin is effective against all the common causal organisms of ophthalmia neonatorum, including the presumed virus of inclusion blennorrhoea.

Local penicillin therapy is likely to replace general sulphonamide treatment as the method of choice in ophthalmia neonatorum.

Thanks are due to Dr. E. N. Young, of the Southern Group (L.C.C.) Laboratories, for her painstaking bacteriological examinations; and to Dr. Olga Blum, Dr. Rela Bartfeld, the Matron, and Sister Condon, of White Oak Hospital, for their collaboration. I am indebted to Prof. Sir Alexander Fleming for his interest and help.

PENICILLIN TREATMENT OF HAND INFECTIONS

BY

G. J. GROSSMARK, M.R.C.S., L.R.C.P.

AND

L. W. PLEWES, F.R.C.S.Ed.

The local use of penicillin in powder and paste (lanette wax form) in the treatment of hand and finger infections has been shown by Florey and Williams (1944) to reduce the time required to clear up sepsis, to diminish pain, and to save an average of nine man-days for each case as compared with controls. In this series 100 cases of paronychia, pulp whitlow, web-space infections, and suppurative tenosynovitis, in all groups of the population, have been treated with penicillin liquid and cream locally, with results that mainly bear out Florey's findings, but with two main differences—namely, in the results of treatment of osteomyelitis and suppurative tenosynovitis.

Principles of Treatment

In all cases in which incision was necessary general anaesthesia was used, and a blood-pressure cuff to give a bloodless field. There was no soaking of the fingers or application of heat of any kind. Penicillin was applied either in liquid form or as a cream on a fine-mesh gauze wick. The cream consisted of penicillin mixed with a base—eucerin L.M. The penicillin in this cream was found by our pathologist (Dr. Seiler) to keep its potency for a longer time than the penicillin in lanette wax. The dressings were all done in a special dressing unit; the dresser used the "no-touch technique," and modern methods of prevention of cross-infection were employed. Of the total 100 cases (representing over 500 dressings) the number of times a second organism was grown was 19. Cultures were taken at the time of operation, and sensitivity to penicillin was tested. Cultures were also taken as a routine at the change of each dressing.

Dressings were done once daily if liquid penicillin was used, or every two days with penicillin cream, since it had previously been found that, although liquid penicillin in an open wound lost its activity in about 24 hours, when cream (penicillin–eucerin L.M.) was used penicillin activity could still be demonstrated at the end of 48 hours.

Surgical procedures in all groups followed orthodox lines, except in the treatment of acute suppurative tenosynovitis. In this condition previous experience with orthodox incisions was so discouraging that a new technique was used. It was based on the observation that acute pyogenic infection of joints responded dramatically to repeated aspiration of the infected fluid and injection of penicillin liquid. None of these fingers was incised.

Results

Pulp Infections.—Thirty-six pulp infections arrived at the hospital, having had throbbing fingers for an average of seven days. In every case the organism was a sensitive *Staph. aureus* (coagulase-positive). In three-quarters of these cases the operation was the usual bilateral incision, and the remaining quarter had either the "hockey-stick" or the "fish-mouth" incision. None of these cases was treated as an in-patient, nor was any splinting done, and the average number of dressings was six. In about half the cases sloughing was present to an extent that mechanical removal was required, and here the time taken to heal was twice as long as when sloughing was not a feature. The occurrence of sloughing seemed to bear no relation to the length of time before operation. The average number of days to "no growth" was 9, and the period off work 17. All the end-results were good.

Paronychia.—There were 32 cases in this group. In all except four the causative organism was *Staph. aureus* (the others, *Str. pyogenes*). Fourteen of these cases had pus under the nail by the time they were first seen, and enough nail was removed at operation to allow access of the penicillin cream to all the infected area. The average time before being seen at hospital was 10 days. In just over half the operations it was found necessary to open the finger on both sides. In the remainder one lateral incision sufficed. On one occasion the pus could be aspirated through a needle, followed by penicillin injection through the same needle. Dressings were done at 48-hour intervals, and on an average four dressings were required. For all this group the average number of days off work was 12; the average number of days before a sterile culture was obtained was 5. The final result was satisfactory in every case.

Web-space Infections.—This group contained 23 cases, and the average time before treatment was 11 days. The operation consisted of an incision between the distal crease of the palm distally to the beginning of the web. Fourteen of these cases were infected by a sensitive *Staph. aureus*. The average time to "no growth" was 9 days and off-work 19 days; each case required on an average seven dressings. Sloughing as a prominent feature was present only once, and chemotherapy was used on two of four patients admitted (because of lymphangitis or adenitis).

Tendon-sheath Infections.—There were nine patients who had an acute suppurative tenosynovitis affecting one of the fingers for an average of four days, the organism in six cases being *Staph aureus*, in three *Str. pyogenes*. None of these fingers was incised; instead, pus from the sheath was aspirated opposite the proximal phalanx, and after aspiration of all that was possible 1 or 2 c.cm. of penicillin was injected through the same needle. The puncture wound was then sealed off with collodion. No splinting was done, and all of these patients were treated as in-patients; the first five cases were given sulphathiazole for five or six days. Active movements were encouraged from the first, and the relief of pain was dramatic in all but one case. This case failed to respond to treatment, and amputation was necessary because of a fulminating infection of the whole finger. In seven cases the results were perfect after one, two, three, or four punctures of the sheath (at 48-hour intervals). One patient apparently had a perfect result after four treatments (aspiration of pus and injection of liquid penicillin), but a month later had developed a slight flexion deformity of the finger. This has remained stationary, and the finger can be used. The average stay in hospital for this group was seven days, and the time off work 13 days. There was no difference in the clinical course when sulphathiazole was used, and the last four cases (all perfect results) were not given systemic chemotherapy.

Osteomyelitis.—Another group, comprising cases of osteomyelitis, were tried with local penicillin, and although one could get negative cultures in a time not appreciably longer than with the above groups, the clinical course of the disease did not seem to be affected. The results of treatment were uniformly bad. It is difficult to report accurately on this group because, first, amputation was often carried out relatively early; secondly, some of the cases were sent elsewhere for *x*-ray therapy; and, finally, some are still unhealed.

Comments

Early on it was realized that removal of slough helped considerably, and the results show this to be true. After trying trypsin and pyruvic acid it was felt that simple excision with a pair of sharp nail scissors was not only quicker but usually more effective.

When this research was started penicillin at a strength of 50 units per c.cm. was used for a few weeks. Subsequently the strength varied from 50 to 2,000 units per c.cm. From our analysis, the strength of the penicillin employed had no effect on the result.

Many hands were swollen as a result of prolonged soaking, and others (about 30%) had had operations (mostly without anaesthesia) before attending hospital. For all groups the average time before being seen was nine days—longest in the web-infection group, and shortest in the tenosynovitis group, probably because of the severity of the pain and disability in the latter.

The most striking effect of penicillin treatment as compared with other methods was the freedom from pain post-operatively, especially in the tenosynovitis series, and the absence of post-operative complications (spreading infection, lymphangitis, adenitis). The most gratifying finding was the spectacular results in acute suppurative tenosynovitis, a condition attended by distressing results in our hands prior to aspiration-injection therapy.

Conclusions

Penicillin used locally is effective in the treatment of infections of the fingers, such as pulp whitlow, paronychia, and web-space infections, when the organism is susceptible.

It is possible to get perfect results in the treatment of acute suppurative tenosynovitis of the fingers by aspiration of the sheath and injection of penicillin.

It is important to remove slough when using penicillin locally.

Local penicillin has no apparent beneficial effect on the end-result in acute osteomyelitis of the phalanges.

Penicillin cream (in a new base—eucerin L.M.—Dr. Seiler) is an improvement on other methods of applying penicillin locally.

INFECTED BRONCHIECTASIS TREATED WITH INTRATRACHEAL PENICILLIN

BY

H. B. MAY, M.D., M.R.C.P.

Assistant Director, Clinical Laboratory, London Hospital

AND

M. A. FLOYER, M.B., M.R.C.P.

Medical Registrar, London Hospital

In most cases of bronchiectasis there is a secondary infection of the dilated bronchi and bronchioles. It is rare for this to be caused by one organism, but the mixed flora in the sputum often includes bacteria susceptible to the action of penicillin, and it was thought that this antibacterial chemotherapeutic agent might have a beneficial effect in the treatment of the disease. It is clear that, in general, a reduction in the bacterial infection of the bronchiectatic cavities, or even their sterilization, although reducing the volume of sputum, would not affect the deformity of the air passages, and infection would recur, but the improvement in the patient's local and general condition might enable a lobectomy to be carried out with a considerable reduction in the operative risk.

Although penicillin would be fully active in the presence of pus, the coexistence of a mixture of organisms of varying susceptibility implies the desirability of obtaining a relatively high concentration of penicillin in the cavities; this cannot, in our experience, be obtained by systemic treatment. An aerosol containing penicillin, as used by Knott and Clark (1945), would probably be equally ineffective because of the deficient aeration of the collapsed area of lung connected with the dilated bronchi. It was therefore decided that the best method of getting adequate penicillin to the infected area was by injection of a solution into the trachea, using a technique similar to that employed in carrying out bronchography.

Technique

The patient practised postural drainage for 20 to 40 minutes before the injection. The skin was rendered analgesic with 2% procaine in the midline of the neck, between the cricoid cartilage and the first ring of the trachea. 2 c.cm. of 2% amethocaine hydrochloride (decicain) was then injected rapidly through a No. 14 needle into the trachea and the patient was asked to try to avoid coughing. The syringe was removed from the needle, which was left *in situ*, and the patient was placed in such a position that fluid introduced into the trachea would run into the bronchiectatic cavities—e.g., well over to the left if the left lower lobe is affected. A solution of penicillin containing 10,000 units per c.cm. was prepared and 5 to 8 c.cm. injected rapidly through the needle into the trachea, the needle being immediately withdrawn and the patient encouraged not to cough. The patient was kept leaning in the appropriate position for 15 minutes after the injection. It was found that with an injection of 50,000 units the sputum coughed up 12 hours after the injection contained between 10 and 100 units of penicillin per c.cm., and with the larger doses of penicillin—i.e., 80,000 units—the sputum after 24 hours still contained up to 10 units per c.cm. Daily treatment was carried out for eight to ten days, and the only complaint from the patients was of some soreness of the skin of the neck. All solutions were made up in saline, and a very fine needle could therefore be used.

Case Records

Case 1.—The wife of a publican was admitted to hospital on Oct. 15, 1944, complaining of pleuritic pain in the right lower chest and general malaise. She had had a perforated duodenal ulcer three months before; this had been sutured under inhalation anaesthesia, but owing to war conditions no details of her immediate post-operative progress are now available. Since the operation she had had recurrent colds and cough, with sputum, and a general feeling of malaise and undue shortness of breath on exertion. On admission it was found that she had coarse crepitations at both bases, with a pleural friction rub at the right base. After two days a small pleural effusion appeared on the right side; this resolved in one week with rest in bed. However, the moist sounds and bronchial breathing persisted at the left base, and a radiograph indicated some fibrosis in this area. Bronchograms revealed an early cylindrical bronchiectasis at the left lower lobe. Her sputum, which was fairly copious, averaging 1 oz. to 2 oz. a day, was purulent and non-offensive, and culturally showed a predominant growth of a pneumococcus sensitive to penicillin; no tubercle bacilli were present. Her haemoglobin was 86% (100% = 14.9 g. of haemoglobin), and she had a normal white cell count. Her sedimentation rate was the upper limit of normal. She was treated with postural drainage in hospital with some improvement in symptoms, but she still produced copious sputum. Intratracheal penicillin was then started, consisting of 50,000 units of penicillin intratracheally for 3 days and 80,000 units for the next 5 days. Owing to her domestic responsibilities she was given the second part of the treatment as an out-patient. Her sputum became mucoid instead of purulent, and culture showed only a few colonies of diphtheroids; it decreased in quantity to less than 1/2 oz. a day. After discharge the patient was symptomless for two months and remains well. The sputum is still mucoid, and is coughed up only with difficulty. She is able to do a full day's work.

Case 2.—A housewife aged 32 was admitted to hospital on Jan. 5, 1945, when 7 months pregnant, complaining of undue shortness of breath on exertion and cough with purulent sputum. She gave a history of pneumonia at the age of 14, since which time she had always had a cough with sputum. For one year she had been breathless on even slight exertion; this became worse during her pregnancy. She had lost her appetite and complained of the foul taste of her sputum. On examination she was cyanosed, and in the chest there were signs of bronchial spasm and coarse rales at both bases, more marked on the left than on the right. Bronchograms revealed bronchiectasis in the left lower lobe. Her sputum contained a varied bacterial flora, with a penicillin-sensitive pneumococcus predominating. She was treated with intratracheal penicillin, 60,000 units a day for 10 days. Her sputum remained copious, but was less purulent and less offensive, and aerobic culture showed a steadily decreasing number of colonies, the final specimen being sterile. One unit of penicillin per c.cm. was present in the sputum 24 hours after injection. Her general condition considerably improved, and she had a normal labour without undue shortness of breath or exacerbation of her pulmonary symptoms.

Case 3.—A gatekeeper aged 59 was admitted to hospital on Oct. 20, 1944, complaining of increasing cough and sputum and loss of appetite for five months before admission. He had had osteomyelitis of the right femur and a right lung abscess in 1940, since which time he had always had a cough, with occasional pain in the right chest and copious foul-smelling sputum. The latter had increased in quantity to 8 to 10 oz. a day, and was so offensive that he had lost his appetite; he had also become very short of breath. On examination he was emaciated and utterly miserable; the only relevant physical signs were at the right base, where there were diminished movement, an impaired percussion note, distant bronchial breathing, and coarse rales. His sputum contained a very varied flora, including a non-haemolytic streptococcus, pneumococci, and species of *Neisseria*, fusiforms, and spirochaetes. Most of the organisms were sensitive to penicillin. His haemoglobin was 56%. Radiographs showed bronchiectasis of the right lower lobe. He was treated with 50,000 units of penicillin intratracheally each day for 8 days and then 80,000 units for 5 days. There was marked subjective improvement; the volume of sputum was reduced to less than a third of its previous volume and became inoffensive, he began to sleep well, and his appetite returned. The physical signs in his chest, though less well marked, were still present, and his haemoglobin rose to 84%. He again took a considerable interest in life, and looked forward to having a lobectomy performed, which, as a result of the improvement in his general condition, was thought to be a reasonable risk.

Discussion

These three examples illustrate the types of case in which intratracheal penicillin would be of value. An early case was so improved that the patient declined lobectomy, as she felt there was nothing wrong with her. In the second case the patient was enabled to get over the latter months of pregnancy and delivery without any extra difficulty arising from her chest condition. In the third case a patient who was clearly going downhill was rendered fit enough for lobectomy to be considered.

There would appear to be two uses for this form of therapy: (1) to improve the general condition of the patient before lobectomy; (2) to sterilize the bronchial cavities at regular intervals, especially during the winter. It might be used to replace bronchoscopy with suction or the creosote chamber. Intratracheal therapy should be combined with daily postural drainage, and can easily be performed upon an out-patient. It is inevitable that the cavities will become reinfected with pathogenic organisms, and it is too early to say how long they will remain sterile, but in cases in which the predominant pathogen in the cavities is penicillin-sensitive the treatment does provide a means at least of temporary improvement.

Summary

The technique of intratracheal administration of penicillin is described.

Three illustrative cases are reported in which this treatment was beneficial.

We wish to thank Dr. J. D. Fiddes, medical superintendent, and Dr. J. B. Penfold, pathologist, St. Andrew's Hospital, Billericay, for valued co-operation.

EFFORT SYNDROME IN THE WEST AFRICAN SOLDIER

BY

DERYCK L. H. GODDARD, M.D., M.R.C.P.

Major, formerly R.A.M.C.

There is no reference in the literature to effort syndrome in the West African, nor have I been able to find any paper dealing specifically with this condition in black-skinned people. This paper records 12 cases of effort syndrome in West African soldiers serving with the Royal West African Frontier Force (R.W.A.F.F.), and seen in a general hospital on the Gold Coast between Dec., 1941, and Dec., 1942.

Observations

The signs and symptoms of effort syndrome as tabulated by Wood (1941) were used as a basis for diagnosis, and questions were directed to elicit any of the symptoms not mentioned by the patient. A thorough physical examination was made in each case, and such investigations as examination of the blood for malaria parasites, radiographs of the chest, and erythrocyte sedimentation rates were carried out when necessary in order to exclude a physical cause of the disability.

The symptoms complained of were breathlessness (in all cases), palpitation (in 10 cases), fatigue (9), dizziness, precordial pain, cramps, and sweating (8), headache and frequency of micturition (6), trembling (5), nervousness, insomnia, and paraesthesiae (4), sighs, throbbing in the head, and anorexia (3), flushing, dry mouth, and diarrhoea (1). The symptoms occurred on exercise in all cases and on excitement in four.

Of signs, tremor was present in 7 cases, excessive sweating of axillae or palms (6), nervousness, overacting heart, and resting pulse rate over 100 a minute (5), hyperpnoea or tachypnoea and cold clammy hands (4), asthenic posture (1). Sighing and hyperaesthesia over the site of precordial pain were not noted in any case; flushing cannot be observed in black men. The highest blood pressure recorded was 142/82. The chest expansion, measured at the fourth rib, varied from 3/8 to 2⅝ in., with an average of 1¼ in.; a similar average was obtained in 16 controls, but I have the impression that the West African is a poor thoracic breather and cannot be compared with the European in this respect. A standard of breath-holding for 30 seconds was adopted; six patients failed in this. The average time was 32 seconds, with a minimum of 8 and a maximum of 55 seconds. In 11 controls the average time was 64 seconds, varying between 30 and 110 seconds. I found it difficult to get satisfactory co-operation in this test, but the controls appeared to try harder than the patients, many of the latter breathing before they had any apparent distress or discomfort. An exercise tolerance test, as recommended by the Horder Committee on Effort Syndrome (1940), was carried out. In 8 cases the pulse failed to return to its original rate within one minute after the end of the exercise, and in 3 cases within two minutes. Three patients were distressed after the test.

Case Histories

Case 1.—A Kumasi (Ashanti) Christian, aged 35. Speaks English very poorly. Private in Gold Coast Regiment (G.C.R.). Service 1 year 8 months. Symptoms started 9 months ago in East Africa while doing P.T. Sent to hospital, in which he remained for three months; having 10 injections into the arms and 10 into the buttocks. Had dysentery in E. Africa 2 months before the onset of the present disability. Likes the Army, but "owing to my sickness I want to be discharged and go home." Did heavy work as a farmer in civilian life. Strong and active as a child. Nothing relevant in family history.

Case 2.—A Creole (Sierra Leone) Christian, aged 26. Speaks excellent English. Shorthand-typist before the war. Private in the West African Army Medical Corps (W.A.A.M.C.). Service 1½ years. Symptoms began 6 months ago in E. Africa during P.T. Admitted to hospital, where he remained in bed for a month with a diagnosis of "rheumatic carditis"; malaria parasites were found in the blood. Has remained well on light duty since discharge from hospital, but on one occasion, when he was obliged to do some heavy work, experienced precordial pain and a sensation as if his chest were being clamped. He now feels that physical work might "humbug" his heart. Volunteered for service in the W.A.A.M.C., where his superior education might be of use, rather than risk conscription at a later date into a combatant unit, for which he did not think himself strong enough. Finds Army life "rough." A keen scholar as a child, being a veritable bookworm. "I always had a notebook in my pocket." Passed the Cambridge School Certificate at the age of 14½. Not popular with other children, who were jealous of his scholastic achievements. Not keen on sport. "Cricket is a decent game, but football is all bullying." Family history: nothing relevant.

Case 3.—An Accra (Ga.) Christian, age doubtful—about 45. Speaks English fairly well. Bus-driver as a civilian. Sapper in W.A. Engineers. Service 2½ years. Symptoms started 4 months ago while mine-lifting in E. Africa. To hospital for 7 weeks; received 20 injections into arms and buttocks. Had dysentery while in hospital. Was told that he had heart disease and should not do any hard work. Likes the Army, but is not happy in his unit. Did well at school. At the age of 9 cut his foot while playing football, and has never played since, because he thinks it is too dangerous. (West Africans play football unshod.) Reliant on his parents. Family history not obtained.

Case 4.—An Accra (Ga.) Christian, aged 31. Speaks English fairly well. Carpenter in civil life. Corporal in W.A. Engineers. Service, 4½ years. Symptoms started 9 months ago during an air raid in E. Africa, and has been unable to do heavy work since then. Likes the Army, but is sure that he cannot carry out his duties in his present health. Strong and active as a child, but would not play football, because "you get wounded plenty." Family history: two nephews (twins) have fits; otherwise nothing relevant.

Case 5.—An Ashanti Christian, aged 25. Speaks English well. Lorry driver as a civilian. Private in G.C.R. Service 2 years 4 months. History of 1 year 8 months. Onset of symptoms in E. Africa during P.T. In hospital for 6 weeks. He was told that he should never do heavy work again. Likes the Army, except that his chest troubles him. Did well at school ("I was always clean and smart"); popular with other children, but especially with the clever ones. Had never avoided physical exertion until onset of present disability. Nothing relevant in family history.

Case 6.—An Avatime Christian, aged 22. Speaks English well. Lorry-driver and farmer before military service. Private in W.A.A.M.C. Two years' service. History of 13 months. Symptoms started while serving in E. Africa. Intelligent and active as a child. Does not enjoy football in the Army because "the other side try to injure you." While in E. Africa was much upset by the news of his father's death, the patient being the eldest son, and so responsible for the rest of the family.

Case 7.—An Akim Abuakwa (Fanti) Christian, aged 23. Speaks very little English. Civil occupation, mason. Private in G.C.R. Three years' service. Symptoms first occurred while on the march in E. Africa 9 months ago. To hospital for a month. Has been told by doctors on two occasions that he should not do heavy work again. Has done only light duty since returning to the Gold Coast 2 months ago. Healthy and active as a child, but not especially clever. No relevant family history.

Case 8.—A Kumasi (Ashanti) Christian, aged 28. Speaks English well. Grocer before the war. Driver in W.A. Army Service Corps. Service 2 years 1 month. Nine years' history. Symptoms started while at school, but lasted only a few weeks, being cured by a native doctor. Left school six years ago, and did light work in his father's grocery store. Joined the Army and remained well until 18 months ago, when the symptoms recurred after he had been in E. Africa for 3 months. Attended hospital for 10 months as in-patient or out-patient and received about 20 intravenous injections. Informed that his heart was the cause of the trouble. Did no further heavy work in E. Africa. Has been on full duty since return to Gold Coast 3 months ago. Patient was timid and retiring as a child. Would not stand up to other children, but reported any bullying to the teacher "because we were forbidden to fight." Similarly, he was once assaulted and robbed, but called for his father instead of defending himself "for the man was bigger than I." Was very reliant on his parents. History of abnormality of behaviour in one brother and two distant relatives.

Case 9.—A Twi Christian, aged 35. Speaks English fairly well. Blacksmith. Sapper in W.A. Engineers. Service 2 years. Disability began 12 months ago during service in E. Africa. In hospital for 6 months, but with no improvement. Had 17 intramuscular and intravenous injections. Told by his doctor that his heart and chest were weak. Symptoms have persisted since return to Gold Coast with diagnosis of "V.D.H. and cardiac enlargement." Likes the Army, "but my sickness troubles me too much." Schooling interfered with by ill-health and persistent pain in the ribs. Would not play games at school because they were not properly controlled and he tired too quickly. Avoided quarrels with other children. "It is my habit not to fight; I was born like that." Thirteen years ago drank palm wine in which ju-ju medicine had been placed; he became "nearly mad," and would shout and sing in the street. Cured by fetish priest. Doubtful history of pulmonary tuberculosis in two brothers. (Screening of this patient's chest showed no abnormality in lungs or cardiac shadow.)

Case 10.—An Osu (Ga.) Christian, aged 29. Speaks a little English. Bus-driver as a civilian. Driver in W.A.A.S.C. Service 2½ years. Symptoms started 8 years ago, but stopped when he joined the Army. They recurred 6 months ago, after a lorry accident. Improvement followed treatment by a native doctor, but the disability had become worse again. Dominated by father, who did not like him to mix with other people. Not very clever at school. Did not play football for fear of injury; he used to run occasionally, but not much, because he never won. History of insanity in grandmother.

Case 11.—An Anlo (Ewe) Christian, aged 25. Speaks a little English. Fisherman in civil life. Private in W.A.A.S.C. Service 4 months. Had symptoms for a short time before joining the Army, but they recurred 3 months ago. Is afraid that he may die. Likes the Army, but "my sickness hinders me." Education interfered with by ill-health, chiefly abdominal trouble. Avoided exertion because it would hurt his heart. History of insanity in uncle.

Case 12.—A Krobo (Ga.) Christian, aged 29. Speaks English well. Lorry-driver as a civilian. Signalman in W.A. Corps of Signals. Service 2 years. Symptoms for 16 months. In hospital a year ago for 6 weeks; records of this admission not available. Strong and active as a child. Clever scholar. Nothing relevant in family history.

Discussion

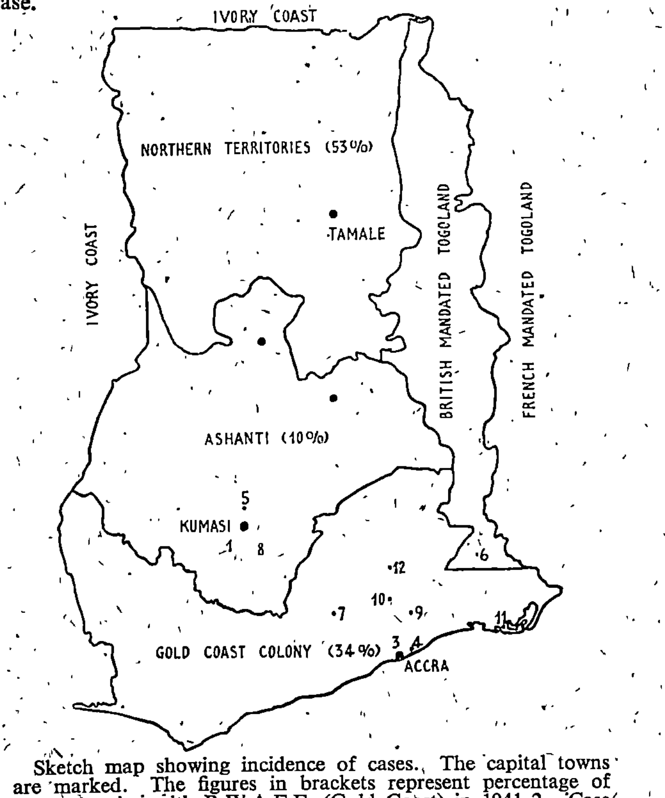
The difficulties facing the physician who attempts a psychiatric investigation of the West African native are very great, and no attempt has been made to diagnose the psychological abnormalities underlying these cases. It will be noted that patients Nos. 2, 4, 8, 9, 10, and 11 were disinclined to exertion from childhood, especially with regard to competitive sport. Two patients (Cases 2 and 8) did light work as civilians, but sedentary occupations are few in West Africa. The first 9 patients had served in the Abyssinian campaign in 1940–1. Factors which may have initiated or fostered the patients' disabilities are:

(a) Acute Fear.—The symptoms in Case 3 started immediately after the man had tripped over and fallen on a mined road, and in Case 4 after the patient had had to run some distance and dive into a slit trench, having been caught unawares by an enemy airplane.

(b) Infection.—Case 2 had malaria parasites in the blood on admission to hospital in E. Africa. Case 1 had dysentery about 2 months before the onset of symptoms, and Case 3 a week after admission to hospital in E. Africa.

(c) Encouragement of Patient's Conviction of Physical Disability.—Cases 1, 2, 3, 5, 7, 8, 9, and 12 had been retained in hospital for periods varying from one to six months. Cases 1, 3, and 9 received many injections, which were almost certainly antispirochaetal. Syphilis occurs in the West African, but yaws is universal. (Kahn tests were positive in four cases in this series.) Patients Nos. 2 and 9 were told that their hearts were affected, and No. 5 that he would never be able to do hard work again; No. 8 stated that his heart had been examined frequently, and that he had been told it was beating too fast. Every patient made spontaneous mention of his heart during the interview or examination.

In order to illustrate the most striking feature of this investigation a very brief account of the geography of the Gold Coast is necessary. The country forms a rough rectangle, about 350 by 190 miles, with its long axis running from north to south, and its base resting on the Gulf of Guinea. It is divided into three parts—the Gold Coast Colony in the south, the Northern Territories (N.T.) in the interior to the north, and Ashanti between the two. British Mandated Togoland skirts the eastern flank of the country. The West African soldiers, recruited in the Gold Coast and serving with the R.W.A.F.F. in 1941–2, were supplied by the three main districts as follows: Northern Territories, 53%; Ashanti, 10%; Gold Coast Colony, 34%; miscellaneous, 3%. The accompanying map shows where the patients in this series lived. It will be observed that, with the exception of Case 2, all the patients hailed from the southern half of the country, and that the Northern Territories, supplying 53% of the native strength, did not provide a single case.



Sketch map showing incidence of cases. The capital towns are marked. The figures in brackets represent percentage of troops serving with R.W.A.F.F. (Gold Coast) in 1941–2. Case Nos. indicate where each patient lived. Case 2 came from Freetown, Sierra Leone.

What is the explanation of the preponderance of cases from the Colony and the apparent immunity of the N.T. man? It is provided, I suggest, in the lower standard of mentality found in the people of the N.T. compared with that of the Colony natives. Not only are the latter a more intelligent people inherently but their mental outlook has been, and is being, changed by contact with Europeans, and there is evidence that this Europeanization is an important factor in determining the liability of the West African to suffer from effort syndrome. European coastal trading posts were established nearly 500 years ago by the Portuguese. European influence was at first confined to the vicinity of such posts, but it gradually spread, and by the Bond of 1844 British "power and jurisdiction" were accepted by many of the tribes living in what is now known as the Colony. To-day a relatively large proportion, although still a minority, of the people in the Colony are European in their outlook; their mode of living and thinking has been affected by close contact with Europeans, and by the radio, cinemas, newspapers, and so on. It is these southern tribes which supply the African lawyers, priests, and doctors, and "black-coated" workers such as teachers, clerks, and accountants. Our relations with Ashanti were of an interrupted and sanguinary nature until, after the Siege of Kumasi, Ashanti became a British colony in 1901, since when European influence has been steadily increasing. It is noteworthy that of the three patients from Ashanti two lived in Kumasi, the capital town and administrative centre, while the third lived only 10 miles north of the town. The Northern Territories became a British protectorate in 1901, but this change has had comparatively little effect on the life of the native.

All the patients under review showed evidence of their contact with Europeans. Thus they all spoke English—only one so poorly that an interpreter was required throughout the interview; but I would estimate that in a general ward an interpreter would be required in at least half the cases if a full history was to be obtained. Further, all these patients were Christians; in a general surgical ward of 40 beds 20 patients were Christians, 15 pagans, and 5 Mohammedans. Huxley (1944), surveying conditions in British West Africa, states: "Not more than one child in about ten gets any education at all," yet only one of the patients had received no schooling. On the whole their intelligence was well above that of the average native of the Gold Coast. I had the opportunity of observing Case 2, the Creole from Sierra Leone, who was posted to the hospital as a nursing orderly, and I found him to be perhaps the most intelligent African in the unit, being secretary to a study circle formed by some of the English-speaking personnel.

The response of the individual to mental conflict and such emotions as anxiety and fear, though depending to a great extent on his innate personality, is also affected by his upbringing, education, and experiences. It is generally accepted that a crude solution to mental conflict—as, for instance, conversion hysteria—is found more often in the less intelligent, while in the more intelligent occur such reactions as effort syndrome, which are subtler and less obviously related to the causative emotion. In the last war Rivers (1918) pointed out that conversion hysteria was more common in the "other ranks" and effort syndrome in the officers, and he suggested that one possible cause may be found in the difference of education, the officer being more widely educated and his mental life more complex and varied. I think it is reasonable to apply Rivers's hypothesis to the Gold Coast West African as between Colony man and N.T. man, taking into consideration the generally lower plane of intellect found in the West African. The patients in this series have, on the whole, been much influenced by "white" civilization. Their sphere of thought has been widened, and their ability to reason increased by knowledge and experience, this process being, of course, accompanied by a repression of the cruder instincts through a stricter mental censorship. The N.T. man still thinks simply, his powers of reasoning are limited, and he is much influenced by suggestion. During the period under review many cases of conversion hysteria were seen in the hospital; I regret that I have no figures or notes available, but I feel safe in stating that the majority of these cases were N.T. men. Certainly I found the language difficulty a great hindrance in getting *en rapport* with these cases, in contrast to the comparative ease with which one conversed with the patients with effort syndrome.

Summary

Twelve cases of effort syndrome in West African soldiers are recorded, and a summary of the case histories is given. Some of the possible predisposing causes are noted. It is suggested that the influence of European civilization is an important factor in determining the incidence of effort syndrome in the West African, and evidence is offered in support of this suggestion.

My thanks are due to Prof. Sir Francis Fraser, and to Dr. G. L. Alexander of the Colonial Medical Service, for criticism and advice; to Lieut.-Col. R. R. Bomford, R.A.M.C., who encouraged me to undertake this investigation; to Major T. Hodgson, M.B.E., R.W.A.F.F., for the figures relating to the enlistment of recruits; and to the Director-General, Army Medical Services, for permission to publish this paper.

Medical Memoranda

Confluent Smallpox Treated with Penicillin

The use of penicillin in the case recorded below was a logical attempt to minimize secondary infection of the very extensive lesions of a severe confluent smallpox. The view that the patient had everything to gain and nothing to lose was encouraged by Prof. J. W. S. Blacklock, of Glasgow Royal Infirmary, to whom I am indebted for the generous supply of penicillin. The diagnosis was one of great simplicity, and the prognosis was given as the gravest possible by Sir Alexander Macgregor, medical officer of health, Glasgow, Dr. R. J. Peters, deputy medical officer of health, and Dr. J. Watson, medical superintendent, Robroyston Hospital, Glasgow.

Case History

The patient was an unvaccinated merchant seaman aged 38. He presumably contracted smallpox in a North African port, but the disease did not develop until he was at sea, bound for home. In the morning of March 26 he shivered repeatedly, and complained of headache, pains in the limbs, and sore throat. He was isolated in the ship's hospital, there being considerable fever and constitutional upset. The eruption began to appear on the forehead late on the 28th. He was removed to Robroyston Auxiliary Hospital on March 30, shortly after the ship reached port.

He was afebrile when seen on admission, and seemed only moderately ill. The eruption was very pronounced over the whole body. On the face it was made up of coalescing vesicles of large size. The scalp was markedly involved, though confluence was not so complete. There were numerous vesicles on the mouth, palate, and gums, especially so where teeth had been removed. Some degree of laryngitis could safely be attributed to lesions in the respiratory passages. On the trunk the rash was profuse and was papular and papulo-vesicular. On the wrists and hands it was practically confluent, particularly over a scar on the left leg. The trunk had very numerous lesions, there being many even on sites usually free of eruption. Of the lesions in general it can be said that the areolae were marked on the head and neck and less so elsewhere.

It was expected that a stormy illness would follow a rash of such profusion, and accordingly penicillin was given by intramuscular injection, it being feared that delirium might interfere with a continuous intramuscular drip. He was given 20,000 units of calcium penicillin early on March 31, by which time he was again sharply febrile. The injections were repeated every fourth hour, and later, as the rash matured, every third hour. By April 4 it was obvious that the illness was not likely to prove as severe as had been expected, and, the patient being fully co-operative, a continuous intramuscular drip was started, which gave him considerable relief. He received 100,000 units daily till April 7, by which date he was free of all constitutional upset and in fact convalescent, it being the 13th day since the onset. In all he received 800,000 units of penicillin. The highest temperature was 101.8° F., recorded on the 8th day of illness. Thereafter there was a steady fall by lysis. At no time was there any feature of clinical interest in the heart, lungs, or urine.

Comment

The evolution of the rash presented some points of interest. On the face it followed a fairly classical course, becoming a wholly confluent pustular mask. Crusting and desiccation were, however, pronounced by the 7th day of efflorescence, or the 9th day of his illness. Thereafter the skin of the face cleared rapidly. Facial oedema lasted no more than 24 hours, and was never very severe. At the time of his discharge, on April 25, there was no evidence of excess granulation tissue, and pitting promised to be minimal. On the trunk and limbs two features were noticeable: most of the lesions failed to increase in size after starting penicillin therapy, and most of them crusted, without going on to pustulation, on or about the 6th day after the eruption first appeared. Desquamation was complete everywhere except on the palms and soles by the 13th day of the eruption, or the 15th day after the onset of the illness.

It is not suggested that penicillin alone was responsible for the happy issue. It is well recognized that the immunity responses may so alter that the outcome of such an illness may well transpire to be other than that first envisaged. Nevertheless I am convinced that penicillin in this instance achieved all that was expected of it, whereas in comparable illnesses of previous outbreaks the intensive use of sulphonamides failed to prevent several fatalities. With the probability of further virulent smallpox reaching our ports, it may well fall to others to confirm the impressions gained from the treatment of this patient.

Millerston.

Empyema complicating a Pneumothorax treated with Penicillin

The following case is interesting in that a pneumothorax occurred as the result of swallowing a safety-pin and a cure was effected by the use of penicillin.

A girl aged 2 years was admitted to hospital on Dec. 17, 1944, having swallowed a safety-pin, which lay point upwards opposite thoracic vertebrae 6 to 8. The pin was removed by a rotatory movement (in the absence of a pin-closer), and as injury to the oesophagus was suspected the patient was started on a course of sulphathiazole.

A radiograph taken on Dec. 18 showed a right-sided pneumothorax. Nothing except the sulphonamide was given by mouth from Dec. 19 to 22, and the pneumothorax did not increase in size after Dec. 20. The patient now appeared well, but on Dec. 23 there was a dullness at the right base, and a radiograph taken on Dec. 27 showed a small pleural effusion. On Dec. 30 a few c.cm. of thin pus was aspirated, and aspirations were repeated every other day until Jan. 4, 1945, when 50 c.cm. of thick pus was obtained. Culture of this pus showed pneumococci, which were penicillin-sensitive. The temperature ranged between 98° and 100° until on Jan. 1 it reached 101°. On Jan. 2 sulphathiazole was discontinued.

Penicillin therapy was started on Jan. 4, when 60,000 units in 50 c.cm. of normal saline were injected into the right pleural cavity. The injection was repeated on Jan. 6 and 8, and after the third injection the temperature remained normal. 40 c.cm. of thick pus was aspirated on Jan. 11, and a fourth injection was given on that day. This pus and 50 c.cm. aspirated on Jan. 17 were sterile, so that the fourth injection may have been unnecessary. Subsequent radiographs showed gradual expansion of the lung but persistent opacity at the right base, which was interpreted as thickened pleura, as no pus was aspirated after Jan. 17.

The patient was discharged on March 17. On March 27, when seen at the out-patient department, she was well, and a radiograph showed complete expansion of the right lung with a small amount of pleural thickening at the parietes.

Volvulus of Caecum with Reversed Rotation of Mid-gut

Volvulus of the caecum associated with reversed rotation of the midgut is a rare condition, so that details of the following case may be of interest.

Case Report

A woman aged 59 was admitted to hospital on Sept. 8, 1943, and stated that twenty-four hours earlier she had begun to have lower abdominal colicky pains, and that her abdomen had become larger. She had vomited several times and had not passed faeces or flatus since the onset of the pain. One week before the present attack she had experienced a similar pain which had lasted for two hours.

On examination the patient was a thin, frail woman in fairly good general condition. The abdomen was distended and tympanitic, the distension being chiefly central abdominal. Audible peristalsis was present and rectal examination revealed no abnormality. A Ryle's tube was passed into the stomach, and the fluid withdrawn was clear and bile-stained. A diagnosis of large-bowel obstruction was made and operation performed.

At operation under a spinal analgesic a right paramedian incision was made and the following condition found: a volvulus of the caecum, first part of the ascending colon, and lower ileum was present, the volvulus consisting of two turns about its axis. The greatly distended caecum was lying in the centre of the abdominal cavity. When the volvulus had been untwisted it was found that the caecum and ascending colon were mobile and had a definite mesentery. The transverse colon just distal to the hepatic flexure disappeared beneath the mesentery of the small intestine, and reappeared again on the left side. Drainage of the caecum was performed by means of a tube inserted through the terminal ileum, the tube being brought out through a small gridiron incision in the right iliac fossa.

Progress.—The ileostomy tube was removed one week later, and the ileostomy rapidly closed. The patient was discharged from hospital three weeks after operation.

Reviews

A REVOLUTIONARY SCHEME OF LOCAL GOVERNMENT

Physician, Heal Thyself. A Study of Needs and Means. By G. Scott Williamson, M.D. (Pp. 133. 5s.) London: Faber and Faber.

The title of this book gives little clue to its contents. It is a plea for a revolutionary scheme of local government which Dr. Scott Williamson calls "Liberal Socialism," defined as "the government of society by the individual for the individual." He thinks he can reconcile the claims of the community with those of the individual. He gives a clear and dogmatic exposition of this thesis applied in detail to our medical services. The author is a convinced believer in the rights of the individual, which have been neglected by what he calls "monopoly socialism"—government by bureaucracy. Medical services should be primarily local and directed not centrally but by the residents in the area, who could be trusted, if the means were provided, to see that good medical service would be forthcoming. His experience as medical director of the Peckham Pioneer Clinic has inspired many suggestions which seem reasonable, however Utopian they may appear at first. The overriding duty of the doctor is "to protect his patient," as his "counsel for the defence"; therefore the patient must have his own doctor, and not the State's doctor. Local clinical centres are essential, and all practice must be centred there. They must be "fully equipped with the tools and services required for efficient diagnosis and treatment"; staffed by general practitioners, who are the keystone of the whole service; the consultants and specialists are advisers used by the doctor in charge of the patient. Great stress is laid on a *free* transportation service for patients to the centre, to their homes or employment, and to hospital when necessary. So much of the time of doctor and patient might be saved by this as would be equivalent to adding 1/2 or 1/3 doctors to the list, and so enable the new service to start at once. To detect the minor ailments, whose importance he cannot stress too much, all members of the family should be overhauled periodically as at Peckham. These centres must have district hospitals, the beds being under the control of the doctors who send in the patients. "Their own doctor must see them through every illness because only he can assess the success of any treatment." "The sick person is the doctor's *patient* and the specialist's *case*." The specialist would be interested, if perhaps annoyed, by what Dr. Williamson has to say about his real status—viz., that of a technical adviser, on certain aspects of a *case*, to the doctor who is in charge of the *patient*. The future consultants and teachers should be "super-general practitioners" chosen from among those who have "succeeded in, and not retreated from, general practice." They must be elected by the men among whom they work. They would act as teachers and as executive officers, seeing that the instructions of the patient's own doctor are carried out. Patients must be paid their full wages while sick, their places being taken by apprentices and others who are being trained to do that particular work; trade unions should be responsible for this supply. He holds it to be as logical to pay the workers essential for the community, and to keep their jobs open while sick, as it is to do the same for civil and other servants of the Crown. The centres and hospitals should be under the control of lay committees elected by the potential patients in the area, as being the only people who can say whether the service is satisfactory or not. The role of the central Government is to collect the insurance contributions. It is merely the agent of the individual subscriber, and should no more be allowed to spend his money than his bank would be allowed to spend his savings. Subscriptions to the service should be based not on a flat rate but according to means, and these can be ascertained by dividing the income of the family by the number of dependants. "The rich must not be allowed to contract out of any public service." The local share of the money collected must be handed over to the local committees to spend according to the needs of the locality. The patient will pay his own doctor by drawing a cheque on his "local medical bank." He will no longer be a "panel patient" but "a patient with a cheque book." A suitable way for finding out what the doctors in total should receive would be to take their earnings in a year in which they did most work. As to the distribution of the money among the doctors the author is not too clear, for here he strikes the problem of how to distribute a limited pool equitably, and this has defeated all who have tried to solve it. There are patients who are too anxious to be visited and doctors who are too anxious to oblige. This must be met by surcharging the doctors with any excess over the mean, and thus a doctor "whose anxiety exceeded the mean would pay for his idiosyncrasy."

This is a bald outline of new and very interesting proposals undoubtedly attractive to many, both patients and doctors. But it all seems too easy—though the author has no doubt about it. It would certainly be opposed by the State Socialists and by the bureaucracy. The author's general philosophy of "Liberal Socialism" is open to criticism at many points. As one example, he says that "Nature hates dying as fiercely as she loves living." It could just as easily be argued that Nature is quite indifferent and that dying is as much a part of Nature as living.

This refreshing book can be cordially recommended to all interested in the future of medical service. Over and over again Dr. Scott Williamson emphasizes that he approaches this problem on the theory that the primary interest is the *individual* patient. He has no use for schemes whose main solicitude seems to be the community.

ENDOCRINOLOGY OF REPRODUCTION

Female Endocrinology, including Sections on the Male. By Jacob Hoffman, M.D. (Pp. 788; illustrated. 60s.) Philadelphia and London: W. B. Saunders Company. 1944.

It has frequently been observed by reviewers that textbooks of general endocrinology have suffered invariably from the size of the subject, which is so large that it is almost impossible for one man to tackle it with any equality of standard. In many such books one branch of the subject is often excellently described, while others are neglected or treated in a manner which is mediocre or frankly bad. Dr. Hoffman's book is the first exception to this rule which we have met. It is true that he does not claim to treat of general endocrinology, but only of the reproductive aspects, which badly needed a modern textbook. Nevertheless, this is in fact a general textbook, for the author recognizes that the endocrine glands are so intricately linked that it is impossible to treat of one or two without instilling at the beginning a working knowledge of glandular physiology and pathology in general, and stressing throughout the influence of other glands. Thus it comes about that though in this book the spotlight is on the endocrinology of reproduction, the rest of the stage is well lit also.

The surefootedness with which Dr. Hoffman picks his way through the tangled undergrowth of stout brushwood and rotten boughs could be possible only for one whose general knowledge of his subject is great. To read Dr. Hoffman on the endocrinology of sex is to be convinced that he could with equal ease have chosen any other path and have written a textbook equally good with the emphasis shifted to other glands. It is the clear critical sense with which the author discards the rotten wood, and holds fast to that which is good, which gives the book its singular value. The bibliographies are short. Almost equally valuable is the breadth of mind with which he avoids the error of too much "hormone consciousness," seeing endocrine disorder always against the background of general medicine, bearing in mind especially the constitutional, psychological, and neurological factors which lie behind the bald "diagnosis" of too much or too little activity in this gland or that.

In England at least (and we have no reason to believe that it is different elsewhere) the practice of clinical endocrinology has too often been a hit-and-miss business, based on no sound foundation of experiment, over-optimistic and sometimes actively harmful. Worthless mixtures of inactive tissue extracts are still administered, with no benefit to anyone but the manufacturers, by doctors who have seen them "well spoken of in the advertisements." Potent preparations, especially of oestrogens, are injected in a mood of cheery optimism without even the preliminary precaution of a diagnosis. Were Dr. Hoffman's decently critical work on every doctor's desk the sufferers from endocrine disorder would suffer less and some of the hormone mongers would be the poorer.

AEROSOLS

Aerosols in Theory and Practice. By Archibald C. Lock, M.I.E.E. (Pp. 40. 5s.) London: Phantosol Products, Ltd.

An aerosol may be roughly defined as a suspension in air of fluid particles so small that they do not wet a solid surface with which they come in contact. It is now well known that suspension of certain disinfectants in this form is, under certain conditions, a remarkably efficient method of disinfecting air. Whether aerosols of any kind will ultimately be preferred to the use of glycol vapours for this purpose has yet to be seen. Those interested, particularly in the mechanics and physics of this subject will find much information in a booklet entitled *Aerosols in Theory and Practice* by Archibald C. Lock, the technical and research manager of Phantosol Products, Ltd., who manufacture apparatus for producing aerosols. He deals mainly with the theory of the subject, and the conditions necessary for efficient application. There is also a section on the use of aerosols as insecticides.

Notes on Books

For the fourth edition of *Medicine for Nurses* (W. H. Smith and Son, Greengate Street, Stafford, or through any branches; 2s. 6d.) Dr. W. Gordon Sears has carried out many minor alterations while retaining its general form. Cross-references to the author's *Materia Medica for Nurses* are not altogether an advantage, and in general there still seems too much detail for the average nurse. Accounts of the pathology of pneumonia (p. 241) or of the differential diagnosis between diabetic coma and hypoglycaemic coma (p. 366) seem beyond the scope of medical nursing. Dr. Sears might well assert that such knowledge is demanded by the syllabus, and so long as the demands of the G.N.C. remain so complicated this book will be of the greatest value.

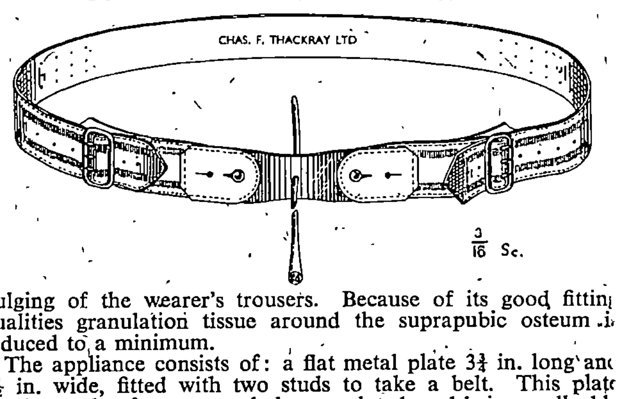
Preparations and Appliances

A METAL SUPRAPUBIC PLATE

Dr. W. Pearce writes from Moortown, Leeds:

The appliance shown in the figure is designed to overcome some of the difficulties experienced by wearers of a rubber suprapubic pad. Rubber next to the skin produces moisture and heat; these thick rubber pads in consequence lead to a friction dermatitis which is very tender and painful to the patient. This condition is entirely eliminated by wearing a metal plate. Being a good conductor of heat it rapidly dispels the heat.

Vaseline or liquid paraffin used to lubricate the catheters cause a curling up of the rubber pads which makes them quite unusable. The metal plate is unaffected by these substances. It fits snugly to the abdomen, is not bulky, and causes no bulging of the wearer's trousers. Because of its good fitting qualities granulation tissue around the suprapubic osteum is reduced to a minimum.



The appliance consists of: a flat metal plate 3¾ in. long and 1½ in. wide, fitted with two studs to take a belt. This plate can be made of copper and chrome-plated, and being malleable can be moulded where necessary to the wearer's abdomen. In the centre is a hole to take a size 18 English gauge standard rubber catheter. This hole is suitably bored so that the catheter is a fairly tight fit. The belt is of webbing of suitable width, lined inside with chamois leather so that it will be comfortable and prevent trouble from friction. It has been found an advantage to have two buckles, one on each side of the appliance over each iliac crest.

This appliance has been made for me by Messrs. Chas. F. Thackray Ltd., of Park Street, Leeds, to whom I am indebted for the able manner in which they have carried out my instructions.

PROGRESS IN THE PSYCHIATRY OF WAR

At this stage in the war, during which we have seen so many great strides taken in both medicine and surgery, it is pertinent to ask what have been the advances made by psychiatry. Development has been as great in this as in other fields; and when we take into account how much less is known of the working of the mind than of the body the proportionate advance that has been made is even greater. There is no need to mention here the progress in treatment of the psychoses, in neuropathology, endocrinology, electro-encephalography, and along many other lines, to which an interesting special number of the *Journal of Mental Science*[1] was recently devoted. The impetus of war experiences has made itself principally felt in the study of personality, normal and abnormal, and of the neuroses. The stresses of war tend to provoke a neurotic type of breakdown, and during this war, as in the last, there has been no increase in the incidence of the psychoses. In a careful study Aubrey Lewis[2] has shown that among civilians the incidence of the neuroses has been surprisingly low—lower than in the Forces, and perhaps little greater than in days of peace. The reason for this is not clear, but it may be related to the end of unemployment, better standards of nutrition, and the provision of a real aim in life. Compared with the men and women in the Forces the civilian has retained liberty of action, allowing him to deal in his own way with the stresses of enemy action.

Numerous studies[3-7] have contributed to our knowledge of the clinical features of neurotic breakdown. All observers agree that there are symptomatic differences between the neuroses of the last war and this. In recent years anxiety neuroses and reactive depressive states have predominated, whereas in the last war the commonest neurosis was conversion hysteria, and anxiety states were principally confined to officers. The same observation has been made in Germany, where it was attributed to the National Socialist ideology.[8] In this country the difference has been attributed to a generally higher standard of education of the public; but it may also be the result of a higher standard of education among medical officers, who are now prepared to admit that a man may be ill with anxiety, and no longer require that he should be hysterically blind, deaf, or paralysed before admitting that the mind may react harmfully on the body. "Disordered action of the heart"—a favourite diagnosis in the last war—has given place to 'effort syndrome"; and now that that has been shown by Paul Wood,[9] Lewis,[10] M. Jones,[11] and others to be in every respect the equivalent of an anxiety neurosis it too has lost favour and has become a rare diagnosis. No longer do we talk of "shell shock": the organic approach has given place to such a preference for psychological interpretation that, with one exception (Anderson[12]), there have been no descriptions of the abnormal neuropsychiatric states that certainly arise from blast injuries. But such states as the result of head injury have been studied very closely, as appears from the recent review by E. Guttman.[13] At a varying time after the injury a syndrome of headache, giddiness, and nervous instability (Symonds[14]) is likely to emerge, particularly in the elderly and the neurotically predisposed. These symptoms tend to come and go in a way closely related to circumstances, and may even appear to be hysterical in nature; but the importance of the organic substratum is not now doubted.

Bodily changes of a reversible physiological kind may also help to bring on neurotic syndromes, especially in the acuter war neuroses, as has been emphasized by Sargant.[15] Many acute anxious and hysterical syndromes, apt to arise in men exposed to heavy bombing and shelling, do not appear before there has been physical exhaustion by loss of weight and lack of sleep. Treatment by securing some days of sleep and building up the general physical state with abundant food and doses of insulin has proved very successful. Prophylactic sedation may also be of value in saving the man in the line who has begun to show signs of wear.[16-18] The main external causes of breakdown in battle are, however, psychological strain and tension. Symonds[19] has shown that in aircraft crews the effects of anoxia, of acceleration, and of decompression are not so important as the emotional tension resulting from the prolonged exercise of courage. Lord Moran[20] has emphasized the same point: courage is a capital account, on which big and repeated drafts can be made only at the risk of bankruptcy. Symonds[21] points out that there is another side: a man may become conditioned to the stimuli which arouse fear in the tyro, so that in him they lack their usual effect. Symonds has gone some way to interpreting these effects in the light of the interplay of excitatory and inhibitory mechanisms in the C.N.S. The emotion of fear is a normal one, and the stresses of war are such as to have their effect on normal men, who can thereby become neurotic. There is, however, much individual variation in susceptibility to stress. According to the Slaters[22] men vary in the degree to which they are predisposed to breakdown in much the same way as they vary in height or intelligence. Big deviations from the average are rarer than smaller ones; and men who are very short or very panicky, or on the other hand are tall or immune to anxiety, are rare in proportion to the degree to which they show these characteristics. These quantitative individual differences may well be determined in part by heredity. Differences in the type of neurotic response are associated with differences in bodily build. W. L. Rees and Eysenck[23] [24] have found that the broadly built and sturdy are more likely than others to show hysterical reactions, while the relatively tall and narrow are more prone to anxiety reactions and effort syndrome.

From the point of view of the armed Forces the neurotically predisposed have to be weeded out from combatant duty. This is but one of the problems that face departments for selection of personnel. Men have also to be chosen for the occupations that will suit them best, and the best men have to be chosen for these occupations by a system of priorities. All duties in the Forces tend to become more and more specialized, and the round peg is less likely to break in a round than in a square hole. The work done along these lines is still secret history, but considerable success has been attained.[25] [26] Perhaps the most important part of prophylaxis is played by good training and the maintenance of corporate morale. However, even here the doctor can help (Spiegel[27]). Once a man has begun to show the first signs of breakdown he must be treated as rapidly as possible. Quite a different type of psychiatric organization has accordingly been built up in this war from that available in the last. Treatment has been predominantly in units near the front line instead of far away at the base. Apart from the physical methods already mentioned, abreactive techniques such as narco-analysis[28-31] have proved valuable. While reduced to a semihypnotic state by barbiturates or ether the man is forced to re-live the frightening experience which precipitated breakdown; recovery of lost memories, disappearance of panic states, and abolition of battle dreams may be obtained with little demand on the doctor's time. It seems that these traumatic neuroses are not entirely inaccessible to psychoanalysis,[32] but owing to the size of the problem short-cut methods have to be employed. The need for economy of time has led to group psychotherapy,[33] in which large numbers of men may at the same time be taken over their problems, so many of which are held in common. The acceptance by one man of a reasonable explanation has its effect on all the others. When the psychiatric history of the war comes to be written it will make a fascinating chapter and be full of lessons for the psychiatry of peace.

CHEMICAL DISINFECTION OF THE AIR

The war which brought into being underground communal dwellings for civilians and overcrowded training camps for Service men and women has given a great impetus to studies on the mode of spread of respiratory infections and on methods for their control. The older conception that respiratory diseases are spread only by direct droplet infection requiring close contact has given way to the view, supported by an increasing volume of evidence, that infected dust and droplet nuclei which carry the infecting agents a considerable distance from their source are also important vehicles. In other words, air, like water, can be polluted bacterially as well as chemically, and in any inhabited intramural environment "respiratory" infections may be acquired without direct contact with a human reservoir. The risk will be greatest where the load of infection is heavy, due either to a high proportion of carriers or to overcrowding; or where the community at risk contains a large number of susceptibles. Thus, hospitals for infectious diseases, children's wards, schools, barracks, transport vehicles, and places of assembly will be the main depots for the dissemination of air-borne infection, and practicable methods of control will have to be applied at these focal points if the incidence of respiratory infections is to be materially reduced.

Methods that have already been devised and tested in the laboratory are dust suppression by oiling floors and fabrics, and disinfection of the air by ultra-violet light or by special chemical disinfectants atomized into the air. These methods are now being tested under field conditions, and only this practical experience will tell us what will be their respective spheres of influence. The likelihood is that they will prove complementary to each other, particularly as both physical and chemical aerial antiseptics lose much of their efficacy in the presence of dust. Evidence that oiling of floors and bed-linen[1] and the use of ultra-violet light[2] are efficacious in controlling the spread of respiratory infections has already been published. On the other hand, field trials of bactericidal mists (the earlier name "aerosol" is regarded as a misnomer) have been rare, despite the large amount of experimental work both here and in America. However, technical difficulties are being overcome, and reports on the value of chemical disinfection of the air in hospitals and in Army barracks are now appearing. Thus Harris and Stokes[3] have carried out an extensive trial of vaporized propylene and triethylene glycols in the wards of a seaside convalescent home for children. Conditions were particularly suitable for testing aerial disinfection; most of the children were confined to bed with rheumatic infection or for orthopaedic treatment, so that direct droplet infection was minimal. There was little ward traffic and the children were out on the balconies during warm periods; infected dust was therefore probably not a serious factor. The six test wards were al identical except that three were on the ground floor anc three on the first. Propylene glycol was used in the firs two winters and triethylene glycol in the third winter. Th glycols were vaporized by immersion of an electric resistance coil in a beaker containing the fluid, and the vapou was dispersed by electric fans. One ward of a pair wa treated with the aerial disinfectant for a 3-weeks period followed by a 3-days break to allow any incubating infections to declare themselves; then the other ward was treate while the original treated ward served as a control. A record was kept of all upper respiratory infections, classified as coryza, nasopharyngitis, tracheobronchitis, and otiti media. Over a total period of 81 ward-weeks there were 13 infections in the treatment wards and 132 in the control wards—a ratio of 1 : 10. During the winter 1942–3, when the common cold was unusually prevalent, only 3 instances of coryza were reported in the treated wards and 79 in the untreated group; the incidence of other respiratory infections in the same period was respectively 2 and 21. The concentration of propylene glycol in the ward air was around one part in 15 million (0.069 mg./litre) and the relative humidity was 30–60%, which is too low for the most effective use of the glycols. It was not easy to maintain a satisfactory level of triethylene glycol, which, though much more potent than propylene glycol, has apparently a narrow range between bactericidal and precipitating concentrations.

These remarkable results were obtained under almost ideal conditions for the application of aerial disinfection. They suggest that this method of control is particularly useful in virus infections which are spread, perhaps much more than bactericidal infections, by droplet nuclei and which probably require a very small infecting dose. But chemical disinfectants are also effective against air-borne haemolytic streptococci, as Cruickshank and Muir[4] originally showed with resorcinol, and as Robertson and his colleagues[5] have proved by a 65% reduction in their numbers from the use of glycol in Army hospital wards. However, the American workers agree with their British colleagues that dust-suppressive measures are at present the most effective and most practicable method of controlling bacterial respiratory infections in hospitals.

There are still many technical difficulties to overcome and new aerial disinfectants like the lactic acid group[6] to be tested. What is particularly needed in this country are facilities for properly controlled field trials of these new weapons against disease.

X RAYS IN INTESTINAL OBSTRUCTION

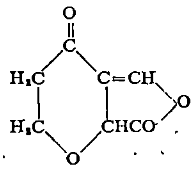
In the whole of surgery there is nothing that arouses greater anxiety than intestinal obstruction. One of the chief difficulties is the recognition of early and incomplete obstruction. Once the diagnosis has been made the main line of action becomes clear. Difficulties may arise later with regard to the amount of pre-operative preparation required, the right moment to operate, the anaesthetic, and the management of post-operative complications, and these decisions call for the exercise of sound judgment founded upon experience; but the whole process, in which the passage of time is of prime importance, will never be set in motion unless intestinal obstruction is first suspected. Confirmation of the diagnosis involves careful analysis of the history, prolonged and if necessary repeated physical examination, and the employment of any special diagnostic methods which may throw light on the problem.

The value of a recent monograph by Dr. Fredrik Koch[7] lies mainly in his assessment of the help which may be obtained from *x*-ray studies of obstruction due to adhesions and bands, though his painstaking and thoughtful statistical inquiries into the causation and results of this form of obstruction are also of much interest and importance. Since adhesions occurring in tuberculosis and cancer are excluded, his 145 cases fall naturally into two groups—those following laparotomy, especially for appendicectomy, comprising two-thirds of the whole, and carrying a mortality rate of 25%; and those without previous laparotomy, most frequently due to a Meckel's diverticulum, with a mortality rate of 36%. Koch advises that, whenever it is possible to do so, *x*-ray examination in the horizontal and vertical positions should be made, attention being paid particularly to the amount of gas in the small intestine. The appearance of fluid levels in the coils of gut is a later sign. He gives as a useful "control" the degree of gas distension found in association with renal calculus, perforated peptic ulcer, and acute appendicitis. Out of 119 patients examined a correct diagnosis of obstruction was made in 109, the mistakes occurring in the earliest stages —within 6 hours of the onset—where the accumulation of gas was minimal. He advises, further, that when operation is not immediately called for a small quantity of barium should be given and followed through, and he gives good pictures to show the arrest of the opaque meal in some of the doubtful cases.

The need for such special methods of diagnosis must be determined by the skill, patience, experience, and judgment of the clinician, but Koch makes out a good case for using *x* rays almost as a routine, and certainly when in doubt. His full review of the literature shows that he is not breaking new ground; but the thoroughness with which he has worked over his own material makes his record a worthy contribution to the subject.

PHARMACOLOGY OF PATULIN

As will be remembered, patulin is a product of the mould *Penicillium patulum*, and it was first described in detail by Birkinshaw *et al.*[1] in 1943. Its structural formula is shown on the right. It appears to be identical with claviformin,[2] clavatin, and clavacin.[3] A concentration of about 1 : 30,000 in glucose broth completely inhibits the growth of Gram-positive and Gram-negative bacteria. Appraisal of its properties was initially distorted by the claim (subsequently disproved) that it possessed curative action for the common cold. It has since been the subject of a very detailed pharmacological investigation by a team of skilled workers, and their recently published reports give an exhaustive account of this aspect of its action.[4]



Patulin appears to be a highly toxic substance, the dose required to kill 50% of the mice treated being 0.5 mg. per 20 g. if injected intravenously, or 0.3 mg. per 20 g. if injected subcutaneously or intraperitoneally: the greater toxicity by these two latter routes is curious. One of its chief actions is to damage the endothelium of the capillaries, causing a widespread and increasing oedema; this is accompanied by general peripheral vasodilatation. It also acts as a general tissue poison, as shown by its toxic effect upon the conjunctiva, upon ciliary movement, and upon the growth of fibroblasts in tissue culture; when applied to superficial wounds it delays healing, and ointments containing a concentration of 1 : 200 cause superficial necrosis. Minor pharmacological properties include a strong anti-diuretic action and a mild general stimulation of the respiratory, vasomotor, and other centres in the medulla oblongata. However, its general toxicity is thought to be too great to permit its therapeutic use. Doubtless all knowledge is valuable, but the investigators deserve our sympathy for having been led after all their careful work to this (clinically) disappointing conclusion. The organization of their research, however, deserves comment quite as much as its results do. The work was carried out as a collaborative study in the laboratories of the Therapeutic Research Corporation and in the Pharmacology Department of Oxford University. It is a good example of co-operation between academic and industrial scientists, such as was previously often described as one of the bases of (former) German pre-eminence in pharmacology and chemotherapy. It is also an omen of the increasingly large part in these fields which will be played by commercial laboratories. Sixty years ago advances in pharmacology depended mainly on the academic scientist working in isolation with limited resources; in the future they will depend much more on large, well-organized teams such as the one responsible for the work described above.

CZECHOSLOVAKIA AFTER LIBERATION

A medical officer of the Czechoslovak Ministry of Health, Dr. A. Kleinzeller, at an U.N.R.R.A. conference in London has given some account of conditions in his country, from which he has lately returned. The main problems encountered in the liberated territory have been epidemics of dysentery, typhus, and typhoid, actual or threatening, and a difficult food and transport situation. The worst conditions were found in Moravia and Eastern Slovakia; in Western Slovakia and in Bohemia they were less severe. In Bohemia, for example, many of the hospitals are standing, whereas in Slovakia they were destroyed by the retreating Germans and Hungarians. The shortage of doctors has presented another urgent problem. In Bohemia and Moravia alone it is calculated that the normal medical population has diminished by one-half. This is due mainly to the exile of many Czech doctors, the departure of German doctors who had practised in Czechoslovakia, and the non-recruitment of students. The University of Bratislava remained open during the five years of the German occupation, but the Universities of Prague and Brno were closed and no doctors could be trained. The University of Prague has now reopened and has had applications from 2,800 students who wish to take up medicine. It has arranged shortened courses for a number of others who had already undergone some training. Dr. Kleinzeller described the German concentration camp at Terezin, about forty miles north of Prague, which he had visited the previous week. This was a camp with a population of 36,000, originally mainly Jewish. The Red Cross took over its protection on May 4, on which date a number of Czech doctors went in to cope with a severe situation arising from outbreaks of dysentery and typhus. The help of the Soviet army medical authorities had to be called in, and they took over the greater part of the task. In the Soviet hospital at Terezin there are now about 2,500 patients, mostly recovering from one or other of the epidemic diseases, and the Czech emergency State hospital has 1,200 more. Thanks to this double effort the epidemic has been stayed, and on the day of Dr. Kleinzeller's visit only five new cases of typhus were notified. In addition to the victims at Terezin a number of people are recovering from typhus in the Prague hospitals. The brighter side of the picture is the quick restoration of services, the resolute handling of the food and transport situation, and the assistance of U.N.R.R.A in the provision of medical personnel and supplies.

SUSPECTED PNEUMOKONIOSIS OF GRAPHITE WORKERS

Pneumokoniosis is a general term used to designate pulmonary reaction to inhaled dust, regardless of the type of dust or the kind of reaction. Certain dusts when inhaled in sufficient quantity give rise to typical pathological changes of the lung tissue—for instance, quartz dust may cause silicosis, and asbestos dust asbestosis. Silicosis was formerly attributed to a mechanical action of the quartz in the lungs, but tissue reactions similar to those of quartz were not produced in animals with diamond, silicon carbide, and other materials harder than quartz. The view is now therefore generally held that silicosis is due to a chemical action of dissolved silica, resulting in a destruction of primary phagocytes and the growth of redundant fibrotic tissue. No material that does not contain silica in some form is known to have a similar effect.

It is against this background that a recent communication by L. Dunner on pneumokoniosis of graphite workers[1] must be considered. Dunner presents skiagrams of five graphite workers which show various degrees of fibrosis The workers had been exposed to pure graphite dust for 17 to 30 years. In contrast to the marked *x*-ray abnormalities there were but few physical signs on auscultation and while three of the men were "chesty" (cough, sputum, shortness of breath) two had no complaints, and all felt fit for work. Dunner quotes Continental experience with workers exposed to graphite or carbon-black dusts, such dusts having been generally considered harmless. He believes, however, that his observations establish the fac that graphite inhalation does produce lesions in the lungs a fact not hitherto described in this country. But it mus be pointed out that in the most striking case, with massive opacities, 30 years of the working life have to be accounte for. Indeed, Dunner states that while no exposure to dus besides graphite was admitted to by any of the five men such exposure cannot be strictly excluded. It should be an invariable rule when describing possible dust lesions to give the occupational histories in detail; unless this is don it is impossible to attribute the lesions to a supposed cause

Graphite is a crystalline modification of the elemen carbon, and may be looked upon as intermediate between well-crystallized diamond on the one hand and amorphou carbon-black or ash-free anthracite on the other. Animal experiments with diamond, anthracite, and other forms of coal have, according to L. U. Gardner,[2] not caused an fibrotic tissue reaction, but V. A. Ravvin and P. A Eniakov[3] say that in animal-dusting experiments coals d bring about a limited change, anthracite more so than bituminous coal. From what is known at present it woul be surprising if inhaled graphite were to have any specifi damaging effect on the lung. To what extent the presenc of inert foreign material will impair lung function, or ho much of it would be required to constitute a hazard, i not known; nor do we know whether it would modif supervening infections. The lack of authentic symptom in the five graphite workers suggests that the "lesions inferred from the skiagrams may be accumulations o graphite, similar to "nodules" of an iron arc welder whic on necropsy were found to be collections of iron particles Knowledge of pneumokoniosis is still incomplete, and is a merit of Dunner's paper to have drawn attention t the *x*-ray appearances of the lungs of graphite worker It is to be hoped that more detailed investigations wi follow.

THE CARE OF THE WOUNDED

An exhibition illustrating the care of the wounded in war is open to the public in the Mall, under the battlements of St. James's Palace, until the end of July. It is presented by the Red Cross and St. John War Organization in collaboration with the Army Medical Services, and sponsored by the *Daily Herald*. It was declared open by the Director-General, A.M.S.

The visitor is first introduced to a model of a battle area made to scale from an ordnance map representing ten miles of country and designed to show the normal lines of evacuation of wounded. Next comes a realistic reconstruction of a regimental aid post three-quarters of a mile behind the line, with battle casualties (life-size models) being brought in by stretcher-bearers and receiving first aid. Beyond this is a casualty clearing post formed by a field ambulance section, with its improved facilities for first aid and for making the patient comfortable for his further journey. A model of the advanced dressing station formed by headquarters of a field ambulance shows the provision for blood transfusion and for other treatment. Then we have a casualty clearing station in which urgent operations are being carried out by a lifelike team of surgeon, anaesthetist, sister, and operating-room assistant. The visitor next passes into a tented ward, supposed to be in the general hospital at the base, where patients spend some time before being invalided home or sent to the convalescent depot. Then there are a number of pavilions illustrating by photographs and models various aspects of the treatment of the wounded, such as the testing and use of penicillin. One pavilion is devoted to the activities of the Army Dental Corps and displays the various types of equipment for dealing with maxillo-facial injuries. Another is concerned with the preventive work of the Army Medical Services, such as the means of ensuring a pure water supply and protection against insect-borne disease. Occupational therapy, for which both the Army medical authorities and the Red Cross provide materials and instructions, is demonstrated in another pavilion. Then the eye is caught by such exhibits as an *x*-ray unit self-contained in its vehicle, a mobile dental unit, and an ambulance car, one of nearly a thousand which the Red Cross and St. John maintain in Army commands in this country and over-seas. One British motor ambulance which is on view has a history. It was abandoned at Dunkirk, and afterwards used by the Germans on both the Russian and Western fronts—it still bears German number plates and military markings—and was recaptured at Commeux last August.

A pavilion is devoted to the innumerable Red Cross and St. John services to the wounded—services which have no precise limits and adapt themselves to any need. They include the making of 13 million hospital garments by an army of 200,000 needlewomen, a library service which has put four million books into circulation among the wounded, 237 auxiliary hospitals in commission at the moment, and ambulances which have travelled eight million miles.

TUBERCULOSIS EDUCATIONAL INSTITUTE

Tuberculosis is a great national problem, and authoritative knowledge is required nowadays not only by doctors and medical students but also by social workers, health visitors, and interested laymen engaged in the campaign against the disease. In the near future new schemes of treatment, research, and restoration to working capacity will increase the need for education and training in modern ideas. Oversea and Empire visitors, doctors, and other health workers require instruction in British methods and antituberculosis measures. As briefly announced in the *Journal* of June 16, the National Association for the Prevention of Tuberculosis and the Joint Tuberculosis Council have formed a new organization, to be called the Tuberculosis Educational Institute, to supply these needs. It will be managed by a committee under the chairmanship of Dr. Frederick Heaf, with the following members: Prof. W. H. Tytler, Dr. A. S. Hall, Dr. A. Morland, Dr. J. C. Simpson, Dr. Norman Smith, Dr. D. P. Sutherland, and Dr. R. A. Young.

The functions of the new body will be: (*a*) to arrange courses, lectures, and demonstrations for the education of doctors, nurses, almoners, and social workers in tuberculosis; (*b*) to act as a centre of information in all matters connected with education in tuberculosis; (*c*) to recommend candidates for N.A.P.T. scholarships to assist doctors, almoners, nurses, and social workers to study tuberculosis; (*d*) to suggest lines of research in tuberculosis; (*e*) to issue a half-yearly index of tuberculosis literature; (*f*) to facilitate and encourage the study of tuberculosis in this country by visitors from over-seas.

The Tuberculosis Educational Institute will help the individual doctor or health worker seeking knowledge on the subject. A register of lecturers and tutors will be formed who will be available to give instruction to workers at home or from over-seas. A managing committee has arranged many successful refresher courses for doctors, health visitors, and social workers, and, with co-operation from postgraduate medical schools, these activities will be extended as opportunity offers to all parts of the country.

The work of the Tuberculosis Educational Institute will be arranged to fit in with the general scheme of postgraduate education now being planned. Its secretary will be the secretary-general of the N.A.P.T., Dr. Harley Williams, who has been placed at the service of the Joint Committee for Education (since its inauguration in 1943) by the Council of the N.A.P.T.

HEALTH AND SANITATION IN RANGOON

Health officers of the British military administration in Burma have announced that Rangoon is free from epidemics. The population is healthier than in any other part of liberated Burma, and has remained fairly well clothed, because of the large stocks of material which were left in the city in 1942. There has been no real food shortage in and around the city. Soap was produced in undamaged local factories, and thus contagious skin diseases, so prevalent in other parts of the country, have not reached epidemic proportions. Another reason for the local population's comparatively healthy condition was the attitude of the Japanese, who, contrary to what they did in most parts of Burma, made some effort to curb disease epidemics in Rangoon, where they came into daily contact with the inhabitants in the docks, munition factories, and supply dumps. Yet the Japanese refused to supply the city's hospitals with drugs; and left behind them large surplus stocks which the British military administration is using for the civilians. They removed the *x*-ray apparatus, although they did not use it themselves, and operations were performed without anaesthetics. To-day, broken sewer pipes have been repaired and the modern compression centre, now working again, has brought a greater part of the city's sewage system into operation. This area includes the crowded business, bazaar, and Chinatown sectors, where hundreds of civilians daily are returning from outlying districts. The 45-mile water pipe-line which brought fresh water to Rangoon—which has always suffered a natural water shortage—is under repair and will come into operation in a matter of days. At present there are sufficient water points in the city to supply the depleted population.

NUTRITIONAL LOSS IN FOOD PREPARATION

The losses of nutrients in the preparation of foodstuffs were the subject discussed at a meeting of the Scottish Group of the Nutrition Society at Dundee on May 19.

Prof. S. J. **WATSON**, of the East of Scotland College of Agriculture, gave a paper on the losses in conserving farm produce, a subject on which, he said, there was a dearth of accurate information. Losses from drying could not be avoided in grains, and in the case of potatoes disease and rotting took a toll; these losses had to be borne by the farmer. Many foodstuffs were still living when placed in store and had to continue to respire in order to live. Respiration involved the giving off of carbon dioxide, which resulted in a gradual loss of weight. In potatoes this loss amounted to about 1.3% per month, so that by the end of June some 15 to 20% had disappeared. The vitamin C in potatoes also fell during storage till it was almost half what it was originally; then it increased again to nearly the full amount just before sprouting began.

Miss **MARY ANDROSS**, of the West of Scotland College of Domestic Science, discussing this problem with special reference to cooking and plate waste, compared the relative loss when eggs were prepared in different ways. In scrambled eggs the loss was 13.5%, in poached 7.5%, and in an omelet 3%. In frying the loss depended on the temperature employed; at 126° C. it was only 1.5%, but at smoking temperature (235° C.) it was nearly 9%. In beef and mutton there was a loss of from 12 to 45% during cooking according to the cut, and plate waste was often very high. There were unexpected differences in the amount of waste between home-fed and imported meats. Losses in vegetables were frequently high, but varied with demand and with the season. Green vegetables were often so wilted when they reached the customer that much had to be rejected. This lack of freshness meant a big loss of vitamins A and C. Some other method of supplying fresh vegetables was needed to avoid the losses of essential elements. The speaker emphasized the importance of home production of vegetables, of increasing market-gardening facilities near towns, and of improving conditions of marketing. Investigations into the plate waste in nine schools showed that it averaged 7% for protein and for fat, but only 1.4% for carbohydrate. Plate waste in the home, on the other hand, was less than 2% for all the primary food factors.

Dr. C. P. **STEWART** said that fruit and vegetables when cooked might lose up to 30% of water and a corresponding proportion of water-soluble constituents. The water-soluble substances were more leached out by boiling than by steaming, and the process was increased by the duration of the cooking. Addition of baking soda.

by raising the *p*H, increased the loss of water-soluble materials, but the increase was not great and was compensated for to some extent by the shorter time required for cooking. Dr. Stewart pointed out that though the percentage losses during cooking appeared large, they might be of little real importance if the figures were small in relation to the total intake, but would be important in the case of certain vitamins which were not available in other foods. Ascorbic acid and aneurin were both subject to destruction during heating; the greatest loss occurred during slow cooking and while the food was kept hot before being served. For example, in April 150 g. of whole potato boiled and quickly served should yield about 10 mg. of ascorbic acid, but if mashed and kept warm for an hour before serving only about 3 mg. might be available. In meats or fish fat loss from liquefaction and leakage might amount to 7 to 20%. In the case of cereals, riboflavin, being relatively stable, was adequately conserved, but aneurin was more readily destroyed, especially when the *p*H was high. The loss was greater when baking powders were used instead of yeast.

Reports of Societies

THE ART OF COMMAND

Lord Moran, P.R.C.P., delivered the 56th Cavendish Lecture before the West London Medico-Chirurgical Society on June 19. His theme was "The Art of Command," and his illustrations were derived from his experiences as a serving officer in the 1914–18 war and as one privileged to have come into close contact with the leaders of the war of 1939–45. The citizen soldier of to-day, he said, unlike the yokel soldier of Agincourt, of whom Shakespeare wrote, "If these English had any apprehension they would run away," was an imaginative person, sceptical also, having been brought up, a child of the last war, to believe that war never settled anything. How was it that such a man had done so well? The effect of discipline, partly, but even more, he thought, *esprit de corps*. The young English officer did not easily become a juvenile Führer: he had an instinctive distrust of coercive measures, and therefore he fell back upon setting an example of imperturbability in the face of danger. Lord Moran recalled how one battalion of the Rifle Brigade had to cross a level space swept by shellfire. An officer dropped his gun and went back to pick it up with the same nonchalance as he would have picked up a dropped glove in the aisle in church. It had an immense effect on the men. That sort of example was infectious.

Of other qualities without which even genius was useless in war, Lord Moran mentioned toughness—the toughness exhibited by Foch: "My right yields; my centre collapses; situation excellent; I attack." But yet another quality was wisdom, a kind of greatness of which Eisenhower was an extraordinary example. Lord Moran found other examples in the Prime Minister and the late President Roosevelt, both of whom were incapable of petty things, and this led him into a personal digression: on an August day in Washington, on the eve of a journey to South Carolina, the President said to him: "You do not know the South Carolina sun. Look after the Prime Minister to-morrow." Next day, under a sweltering sun and amid clouds of dust raised by the tanks, a telegram was put into his hand by General Marshall: "You and Lord Moran are in command. Enough said.—Roosevelt." It was Roosevelt's pleasant way, in the midst of his own preoccupation, of reminding him of his particular charge. No wonder that the Prime Minister had said to him once, when they were walking in an orange garden at Marrakesh: "I love these Americans." When history came to be written the friendship between those two men would be seen to be one of the chief factors in the achievement of these years.

Another quality in command was knowledge of men. Some men who had themselves attained high positions were singularly lacking in their ability to pick the right people. They did not know a man when they saw him. The ability to know what was in a man, almost at a glance, was as invaluable to the commander of an army as it was to a consulting physician who might see a complete stranger every hour. Incidentally Lord Moran said that that was the late Lord Dawson's most extraordinary gift. He remembered being at a consultation with him, and after they had examined the patient they went into a room where there were seven relatives; Lord Dawson seemed to know, before anything was said, what was passing in the mind of each of them and the anxieties to which they were subject. It was no doubt a gift with which one was born; but it could be developed; and the way to develop it was to take an interest in one's fellow beings. Everybody claimed to have the gift of being able to judge his fellows. They would acknowledge that they could not bat like Hobbs or play the violin like Kreisler, but they would claim that they could sum people up. Yet it was one of the rarest of gifts.
